A dissertation

presented at Ryerson University

in partial fulfillment of the

requirements for the degree of

Doctor of Philosophy

in the program of

Molecular Science

Toronto, Ontario, Canada, 2018

AUTHOR'S DECLARATION FOR ELECTRONIC SUBMISSION OF A

DISSERTATION

I hereby declare that I am the sole author of this dissertation. This is a true copy of the

dissertation, including any required final revisions, as accepted by my examiners.

I authorize Ryerson University to lend this dissertation to other institutions or individuals

for the purpose of scholarly research

I further authorize Ryerson University to reproduce this dissertation by photocopying or

by other means, in total or in part, at the request of other institutions or individuals for the

purpose of scholarly research.

I understand that my dissertation may be made electronically available to the public.

REGULATION OF LYSOSOME BIOGENESIS BY

PHOSPHOINOSITIDES AND PHAGOCYTOSIS

Christopher Choy

Doctor of Philosophy, 2018

Molecular Science, Ryerson University

Abstract

Lysosomes are acidic organelles responsible for molecular degradation, energy balance, and pathogen clearance. Consequently, lysosome dysfunction is linked to numerous diseases, including lysosome storage diseases. Notably, enhancing lysosome biogenesis ameliorates cell function and helps clear metabolites. The transcription factor EB (TFEB) is a master regulator of lysosome biogenesis, and thus a potential therapeutic target. Among known regulators of TFEB, the mammalian target of rapamycin complex 1 (mTORC1) is best understood. In nutrient-rich cells, mTORC1 is activated and represses TFEB by phosphorylation. Upon starvation, mTORC1 is inactivated and TFEB enters the nucleus, upregulating lysosomal gene expression to enhance cellular degradation for energy recovery. Numerous other TFEB-dependent pathways have been identified. We aim to understand how TFEB is regulated in two additional contexts: in lysosome enlargement during phosphatidylinositol 3,5-bisphosphate [PtdIns(3,5)P_2] depletion and in phagocytosis.

First, PtdIns(3,5)P_2 is required for maintaining lysosome size by an incompletely understood mechanism. We hypothesized that TFEB-mediated lysosome biogenesis contributes *de novo* lysosomal material. Acute depletion of PtdIns(3,5)P_2-synthesizing

kinase PIKfyve induced TFEB nuclear accumulation. Despite increases in transcription, little to no protein translation was observed. Furthermore, *tfeb*$^{-/-}$ cells and cells blocked with cycloheximide were similar to wild-type cells, with regard to the number and size of lysosomes during PIKfyve inhibition cells, suggesting biosynthesis is not necessary for lysosome enlargement. However, TFEB still becomes active by an known mechanism. We show that TFEB nuclear localization during PIKfyve inhibition was not due to mTORC1 inactivation but may result from GSK3 inhibition.

Secondly, phagocytosis allows immune cells to sequester potential pathogens by engulfing them into phagosomes. These phagosomes are then degraded by the lysosome. We postulated that phagocytosis would enhance TFEB-mediated lysosome biogenesis to promote pathogen killing. Fcγ receptor-mediated phagocytosis activated TFEB and increased biosynthesis of select lysosomal genes, augmenting existing lysosomes and enhancing proteolysis. To understand how TFEB was activated by the Fcγ receptor, we inhibited key signaling and trafficking mediators. Particle internalization, phagosome formation, and phagosome maturation appear to be necessary for TFEB activation.

Overall, our work uncovers two additional mechanisms that may govern TFEB-activation.

Acknowledgements

First, I acknowledge my supervisor and mentor, Dr. Roberto Botelho, whose guidance and support has been instrumental in my personal and professional growth. Thank you for taking a chance on me when I had no experience. Thank you for being patient with me and providing me with tough love that drove me to be my best.

I would also like to acknowledge my graduate committee: Dr. Warren Wakarchuk and Dr. Jeffrey Fillingham for challenging me to do better. Thank you for being a calm voice when I needed reassurance. In addition, I acknowledge Dr. Costin Antonescu who has provided additional mentorship during lab meetings and ad-hoc committees.

I am also grateful for the support provided by the Botelho and Antonescu lab family. Specifically, I thank Amra Saric, Shannon Ho, Grace Kim, and Monica Dayam for their roles in training me. I would also like to thank Dr. Matthew Gray, Golam Saffi, and all the volunteers and thesis students who have contributed to my thesis. Furthermore, I thank Victoria Hipolito, Krishna Chintaluri, Ralph Christian De Los Santos, Camilo Garay, Tracy Lackraj, and all those named above for making my time in graduate school enjoyable.

Finally, I thank my parents, my sister, and my partner, Cynthia Luong, for their unending love and support.

Table of Contents

List of Figures

List of Appendices

List of Abbreviations

4E-BP1 – Eukaryotic translation initiation factor 4E-binding protein 1

AGS3 – activator of G-protein signaling 3

bHLH – basic helix loop helix

CASTOR – cytosolic arginine sensor for mTORC1 subunit 1

CLEAR – coordinated lysosomal enhancement and regulation

CPS – carboxypeptidase S

DAG – diacylglycerol

Deptor – DEP-domain-containing mTOR-interacting protein

EEA1 – early endosome antigen 1

ERK – extracellular signal-regulated kinase

ESCRT – endosomal sorting complexes required for transport

FYVE – (Fab1, YOTB, Vac1, EEA1)

GAP – GTPase-activating protein

GEF – guanine nucleotide exchange factor

GSK3 – glycogen synthase kinase 3

HLH – helix loop helix

HOPS – homotypic fusion and vacuole protein sorting

IgG – immunoglobulin G

IL – interleukin

IP$_3$ – inositol trisphosphate

ITAM – immunoreceptor tyrosine-based activation motif

ITIM – immunoreceptor tyrosine-based inhibitory motif

LPS – lipopolysaccharide

LAT – linker of activated T cells

LZ – leucine zipper

M6P – mannose 6-phosphate

MiTF – melanogenesis associated transcription factor

mLST8 – mammalian lethal with Sec13 protein 8

mSin1 – mammalian stress-activated protein kinase interacting protein

MTMR – myotubularin-related

mTOR – mechanistic target of rapamycin

mTORC1/2 – mTOR complex 1/2

MVB – multivesicular body

NLS – nuclear localization sequence

NPF – nucleation promotion factor

PAMP – pathogen-associated membrane protein

PH – Pleckstrin homology

PLC/PLD – phospholipase C/D

PKC/PKD – protein kinase C/D

PP2A – protein phosphatase 2A

PRAS40 – proline-rich Akt1 substrate of 40 kDa

PRR – pattern recognition receptors

PtdIns – phosphatidylinositol

PtdInsPs – phosphoinositides

PX – Phox homology

RANKL – receptor activator of nuclear factor kappa-B ligand

Raptor – regulatory associated protein of mTOR

Rictor – rapamycin insensitive component of TOR

S6K – ribosomal protein S6 kinase

SH2 – Src-homology 2

SNARE – soluble N-ethylmaleimide-sensitive factor attachment protein receptors

SREBP1 – sterol regulatory element-binding transcription factor 1

SUMO - small ubiquitin-like modifier

Syk – spleen tyrosine kinase

TPC1/2 – two pore channel 1/2

TSC1/2 – tuberous sclerosis protein 1/2

TFE3 – transcription factor E3

TFEB – transcription factor EB

TFEC – transcription factor EC

TRPML1 – transient receptor potential mucolipin-1

TORC1 – target of rapamycin

ULK1 – UNC-51-like kinase 1

V-ATPase – vacuolar ATPase

Vps – vacuolar protein sorting protein

WASp – Wiskott–Aldrich Syndrome protein

Chapter 1: Introduction

1.1 The lysosome

The lysosome is an acidic organelle and degradation center of the cell. The acidic lumen is generated and maintained by the vacuolar H^+-ATPase (V-ATPase). Protons are pumped into the lysosome at the expensive of ATP to a pH of 4.5-5.0. This acidic environment serves as the optimal environment for over 60 hydrolytic enzymes, including proteases, lipases, and nucleases (Schröder, Wrocklage, Hasilik, & Saftig, 2010). The concerted action of these hydrolases leads to the degradation of an array of complex macromolecules into their constituents. These macromolecules can be delivered to the lysosome by a variety of degradative pathways. Extracellular materials can be internalized through receptor-mediated endocytosis, phagocytosis or pinocytosis and are trafficked through the endocytic pathway (described in greater detail below) (Bohdanowicz & Grinstein, 2013). Membrane components can also be trafficked through the endocytic pathway, sequestered and delivered as intraluminal vesicles (Henne, Buchkovich, & Emr, 2011). Finally, soluble cytosolic macromolecules or organelles are delivered to the lysosome through autophagy (Saha, Panigrahi, Patil, & Bhutia, 2018). The resulting degradation products, like amino acids, can then be reused by the cell and transported out of the lysosome through numerous transporters (Schröder et al., 2010). The lysosome is also known to contain many ions and solutes that facilitate other lysosomal functions, including endomembrane trafficking, lysosome exocytosis, and cellular signaling (Xiong & Zhu, 2016).

1.1.1 The lysosome as a signaling hub

Beyond its degradative function, the lysosome participates in signaling by serving as a signaling platform or by activating signaling mediators from lysosomal ions. The most well-known signaling hub found at the lysosome is the mechanistic target of rapamycin complex 1

(mTORC1), which localizes directly to the lysosomal surface (Sancak et al., 2010). This complex is made up of the mTOR kinase at its core, associated with Raptor (regulatory associated protein of mTOR), PRAS40 (proline-rich Akt1 substrate of 40 kDa), mLST8 (mammalian lethal with Sec13 protein 8), and Deptor (DEP-domain-containing mTOR-interacting protein). mTOR can also form a second non-lysosomal complex, mTORC2, when associated with Rictor (rapamycin insensitive component of TOR), mLST8, mSin1 (mammalian stress-activated protein kinase interacting protein) and Deptor (Saxton & Sabatini, 2017). The activity of mTORC1 is dependent on two nutrient-based inputs that converge at the lysosome: amino acids and growth factors.

Amino acids influence the lysosomal localization of mTORC1 by acting on the Rag GTPases (Sancak et al., 2008). These GTPases act as heterodimers in opposing nucleotide binding states. When active, GTP-bound Rag A or B heterodimerize with GDP-bound Rag C or D (Sancak et al., 2008). Dedicated sensors for leucine and arginine sense the abundance of amino acids and influence the nucleotide binding state of Rag A/B. Specifically, cytosolic leucine and arginine are sensed by Sestrin2 and CASTOR respectively leading to inhibition of GATOR1, a GTPase-activating protein (GAP) for Rag A/B (Chantranupong et al., 2016; Saxton et al., 2016; Wolfson et al., 2016). Additionally, amino acids within the lysosome are also sensed. Arginine levels are sensed by the permease SLC38A9 and general amino acids are sensed by the V-ATPase (Rebsamen et al., 2015; S. Wang et al., 2015; Zoncu et al., 2011). Together, these two components activate the Ragulator complex, a guanine exchange factor (GEF) for Rag A/B (Bar-Peled, Schweitzer, Zoncu, & Sabatini, 2012). The Ragulator complex also serves as a docking site for activated Rag GTPases, which brings mTORC1 to the lysosome through interactions with Raptor and Ragulator (Sancak et al., 2010). Once recruited to the lysosome, mTORC1 can

then be activated by growth factors in a Rheb GTPase-dependent manner (Garami et al., 2003).

Growth factor signaling leads to inhibition of the Rheb-specific GAP, tuberous sclerosis complex

1/2 (TSC1/2), leading to GTP-loading of Rheb and activation of mTORC1 (Garami et al., 2003).

In turn, activated mTORC1 promotes cell growth and proliferation by promoting

processes like protein and lipid synthesis. Protein synthesis is stimulated through the

phosphorylation of p70-S6 kinase (S6K) and eukaryotic translation initiation factor 4E-binding

protein 1 (4E-BP1) (Brown et al., 1995; Brunn et al., 1997). Together, these factors upregulate

ribosomes and other components of the translational machinery. Similarly, lipid synthesis is

promoted through the activation and nuclear localization of the transcription factor sterol

regulatory element-binding transcription factor 1 (SREBP1), a transcriptional regulator of lipid

and sterol production (Porstmann et al., 2008). Simultaneously, mTORC1 also blocks catabolic

processes by downregulating autophagy, in part by inhibiting substrates like ULK1 (Hosokawa

et al., 2009).

In contrast to mTORC1, lysosomal ions also play a significant role in cellular signaling

and membrane trafficking. The lumen of the lysosome is a significant storage site for many ions

including H^+, Ca^{2+}, Na^+, Cl^-, and Fe^+ (Xiong & Zhu, 2016). Specifically, the concentration of

Ca^{2+} in the lysosome is around 500 µM, much greater than the cytosolic Ca^{2+} concentration

(Christensen, Myers, & Swanson, 2002). Release of Ca^{2+} from the lysosomal lumen can be

facilitated by transient receptor potential mucolipin-1 (TRPML1) or P2X4 (Bo et al., 2003; Dong

et al., 2010). The efflux of Ca^{2+} from the lysosome to the cytosol through TRPML1 can

participate in cellular signaling by activating the protein phosphatase calcineurin (Medina et al.,

2015). Common to both mTORC1 and lysosomal Ca^{2+}-dependent calcineurin activation,

lysosome biogenesis and autophagy can be controlled at a transcriptional level by regulating the

transcription factor EB (TFEB), a member of the MiT/TFE family of transcription factors (Medina et al., 2015; Sardiello et al., 2009).

<u>1.1.2 The MiT/TFE family of transcription factors</u>

The MiT/TFE family of transcription factors are key biosynthetic regulators of lysosomes, autophagy, and other metabolic processes (Slade & Pulinilkunnil, 2017; Steingrímsson, Copeland, & Jenkins, 2004). In mammalian cells, this family of transcription factors is composed of four members: MiTF, TFE3, TFEB, and TFEC (Hemesath et al., 1994). While MiTF and TFEC are expressed in specific tissues, TFEB and TFE3 are expressed more ubiquitously (Slade & Pulinilkunnil, 2017). Structurally, these transcription factors contain a helix-loop-helix (HLH) domain and a leucine zipper that facilitate homo- and heterodimerization between the family members (Hemesath et al., 1994). The MiT/TFE family exclusively heterodimerize amongst themselves due to a three residue shift found within the leucine zipper, excluding other HLH transcription factors from dimerizing (Pogenberg et al., 2012). They also contain a basic domain that is necessary for DNA binding, specifically towards E-box motifs (5'-CANNTG-3'), characteristic of HLH/leucine-zipper transcription factors (Aksan & Goding, 1998; Hemesath et al., 1994; Massari & Murre, 2000). Despite their similarity, only MiTF, TFEB and TFE3 contain an transactivation domain necessary for transcriptional activation (Beckmann, Su, & Kadesch, 1990). Conversely, TFEC lacks this domain and restricts transcriptional activation when dimerized with other MiT/TFE family members (Zhao, Zhao, Zhou, Mattei, & de Crombrugghe, 1993). These genes also exist in invertebrates, albeit their collective function appear to be carried out by a single homologous gene. *Drosophila melanogaster* have a single MiTF gene (Bouché et al., 2016) while *Caenorhabditis elegans* has

HLH-30 (Visvikis et al., 2014). Of the previously mentioned mammalian MiT/TFE family members, TFEB was the first to be characterized as a regulator of lysosomal gene expression (Sardiello et al., 2009), although others have shown that MiTF and TFE3 can also enhance lysosomal biogenesis in a cooperative manner (Martina et al., 2014; Ploper et al., 2015). Thus, TFEB will be the focus for this thesis.

Analysis of several lysosomal genes identified a common element within their promotor sequence, which the Ballabio group named the coordinated lysosomal enhancement and regulation (CLEAR) motif (5'-GTCACGTGAC-3') (Sardiello et al., 2009). Genome-wide analysis revealed 471 genes with one or more CLEAR motifs that are collectively controlled by TFEB (Palmieri et al., 2011). While some genes are responsible for functions such as vesicular trafficking or immunity, the largest proportion of these genes relate directly to the lysosome and autophagy (Palmieri et al., 2011). Therefore, TFEB is widely regarded as a master regulator of lysosome biogenesis and autophagy. Research has since focused on understanding how TFEB can be regulated and the specific contexts that benefit from modulating lysosome biogenesis.

1.1.3 TFEB in autophagy and mTORC1 regulation

The role of TFEB is best understood under the context of amino acid starvation (Figure 1.1.1). When amino acids are present, TFEB is inactive and restricted from the nucleus. Conversely, when amino acids are withdrawn, TFEB enters the nucleus where it can activate transcription of CLEAR network genes (Roczniak-Ferguson et al., 2012). The details regarding amino acid starvation have been well documented with TFEB subjected to multiphasic regulation.

6

The presence of amino acids promotes the phosphorylation of TFEB at S3 by MAP4K3, mediating the interaction between TFEB and the activated Rag GTPases, where Rag A/B is GTP loaded and Rag C/D is GDP loaded (Hsu et al., 2018; Martina & Puertollano, 2013). The active Rags recruit TFEB and mTORC1 to the Ragulator complex at the lysosome, where mTORC1 is further activated by the GTPase Rheb (Martina & Puertollano, 2013; Sancak et al., 2010). At the lysosome, mTORC1 directly phosphorylates TFEB on at least three residues: S122, S142, and S211 (Roczniak-Ferguson et al., 2012; Vega-Rubin-de-Celis, Peña-Llopis, Konda, & Brugarolas, 2017). The most important phosphorylation site modulating nuclear localization appears to be S211. Phospho-S211 creates a binding site for the chaperone 14-3-3/YHWH, which masks the nuclear localization sequence (NLS) found at amino acids 241–252 of TFEB (Roczniak-Ferguson et al., 2012). As a result, TFEB remains in the cytosol and transcription of CLEAR network genes is restricted.

Conversely, amino acid starvation prevents the activation of Rag GTPases (Martina & Puertollano, 2013). Here, Rag A/B are GDP-loaded and Rag C/D are GTP-loaded. mTORC1 is inactive and cannot phosphorylate TFEB. At the same time, amino acid starvation leads to the efflux of Ca^{2+} out of the lysosome, through the gated-calcium channel TRPML1 (Medina et al., 2015). Release of Ca^{2+} activates the protein phosphatase calcineurin, responsible for dephosphorylation of TFEB at S211 (Medina et al., 2015). Without phospho-S211, 14-3-3 cannot bind to TFEB and the NLS becomes exposed (Roczniak-Ferguson et al., 2012). Nuclear translocation of TFEB may be facilitated by importin-8 (Perera et al., 2015), where TFEB enhances transcription of CLEAR network genes. Therefore, increasing TFEB-mediated lysosomal biosynthesis promotes degradation of autophagic cargo to be recycled by the cell.

Beyond nutritional stress, TFEB activation appears to have significant implications towards numerous cellular stressors, many of which rely on mTORC1 independent routes (Figure 1.1.2).

1.1.4 Regulation of TFEB by phosphorylation

There are at least six kinases and two phosphatases that can directly modulate TFEB phosphorylation thus far (Puertollano, Ferguson, Brugarolas, & Ballabio, 2018). Like mTORC1, many phosphorylation events can control subcellular localization of TFEB. One such kinase is Akt, that phosphorylates TFEB at S467 and was investigated as a therapeutic target towards neurodegenerative diseases, including Huntington's disease, Parkinson's disease, and Alzheimer's disease (Palmieri et al., 2017; Sarkar, Davies, Huang, Tunnacliffe, & Rubinsztein, 2007). These neurodegenerative diseases stem from the accumulation of aberrant protein aggregates in their cytosol that are typically cleared by autophagy. Thus, disruption to autophagy has been linked to disease on-set (Nixon, 2013). Many neurodegenerative diseases also appear to have impaired or insufficient TFEB activation. (Decressac et al., 2013; Polito et al., 2014; Xiao et al., 2014). To enhance autophagy in neurons, TFEB can be targeted by inhibiting Akt with trehalose, a non-reducing disaccharide (Palmieri et al., 2017; Sarkar et al., 2007). Akt inhibition with trehalose leads to TFEB dephosphorylation at S467 and nuclear localization, independently of mTORC1 (Palmieri et al., 2017).

Another kinase responsible for modulating TFEB localization is the glycogen synthase kinase 3 β (GSK3β), which directly phosphorylates S134 and S138 (Y. Li et al., 2016; Marchand, Arsenault, Raymond-Fleury, Boisvert, & Boucher, 2015). Inhibition of GSK3β leads to TFEB nuclear translocation, enhancing autophagy in cancer cells and neurodegenerative disorders (Y. Li et al., 2016; Marchand et al., 2015). Here, GSK3β may specifically regulate

TFEB nuclear export (L. Li et al., 2018). Interestingly, TFEB has long been known to be associated with renal cell carcinoma due to chromosomal rearrangement, leading to TFEB overexpression (Argani et al., 2016; Kuiper et al., 2003). While TFEB activation may induce some cancers, TFEB activation is necessary to induce cell death in other cancers (Gayle et al., 2017). Nevertheless, the effect of GSK3β on TFEB can further be regulated upstream by protein kinase C-α (PKCα) or PKCδ (Y. Li et al., 2016). Here, enhanced PKCα or PKCδ activation can phosphorylate and inhibit GSK3β, leading to TFEB activation.

Certain isoforms of PKC may also have important roles in TFEB-dependent immune function, including PKCα and/or PKCγ. Mouse macrophages challenged with *Salmonella enterica* or *Staphylococcus aureus* induced TFEB nuclear localization (Najibi, Labed, Visvikis, & Irazoqui, 2016; Visvikis et al., 2014). This effect depended on the activity of multiple signaling regulators including phosphatidylcholine-specific phospholipase C (PLC), protein kinase D (PKD), and PKCα and/or PKCγ, independently of mTORC1 (Najibi et al., 2016). The authors speculate that this pathway may be downstream of G-protein coupled receptor activation (Najibi et al., 2016). Consistently, the activator of G-protein signaling 3 (AGS3) appears to increase expression upon stimulation with lipopolysaccharide (LPS) or live bacteria (Vural et al., 2016). However, contrary to the previous study, the effects of AGS3 appear to inhibit mTORC1 through inhibition of the Rheb via TSC1/2, similar to growth factor signaling (Vural et al., 2016). Nevertheless, immune signaling appears to be a potent activator of TFEB activation.

Other PKC isoforms can also regulate TFEB. Osteoclasts are bone absorbing cells that rely on lysosome exocytosis for reabsorption. Cytokine activation by receptor activator of nuclear factor kappa-B ligand (RANKL) in osteoclasts induces PKCβ activation and phosphorylation of TFEB at S462 and/or S463, S466/S467, and S469 (Ferron et al., 2013).

Interestingly, TFEB phosphorylation by PKCβ stabilized the protein and total cellular accumulation of TFEB (Ferron et al., 2013).

Additionally, TFEB activation appears to play significant roles in the cell's response to other stressors. Induction of mitochondrial stress (Ivankovic, Chau, Schapira, & Gegg, 2016; Nezich, Wang, Fogel, & Youle, 2015), endoplasmic reticulum stress (Martina, Diab, Brady, & Puertollano, 2016), or oxidative stress (Martina & Puertollano, 2018) can all induce TFEB activation. During oxidative stress, S211 becomes dephosphorylated by protein phosphatase 2A (PP2A), inducing TFEB nuclear localization (Martina & Puertollano, 2018). PP2A activity may also be activated during long term fasting in animal models, leading to TFEB dephosphorylation (Chen et al., 2017). S211 is not the only phospho-site with multiple regulators. The extracellular signal-regulated kinases 2 (ERK2) was suggested to phosphorylate S142, which prevented TFEB nuclear localization (Settembre et al., 2011). However, the exact role of ERK2 on S142 phosphorylation is not well understood as follow up studies with an ERK specific inhibitor did not induce TFEB activation (Settembre et al., 2012).

1.1.5 Regulation of TFEB by other post-translational modifications

While phosphorylation remains the dominant post-translational modification determining TFEB localization and stability, other post-translational modifications appear to alter activity of the transcription factor within the nucleus. Sumoylation was observed in MiTF, TFEB, and TFE3 (Miller, Levy, Davis, Razin, & Fisher, 2005). The addition of small ubiquitin-like modifier (SUMO) to lysine residues altered their ability to bind specific promoters. Sumoylated MiTF at K182 and K316 displayed stronger binding to promoters with multiple E-box sequences, but was not required for heterodimerization or nuclear translocation (Miller et al., 2005). TFEB appears

to retain a single sumo-site at K347, which was analogous to K316 of MiTF by sequence alignment (Miller et al., 2005). Additionally, acetylation of TFEB was also observed. Deacetylation at K116 by the nuclear deacetylase SIRT1 enhances TFEB-mediated transcription and promotes clearance of fibrillar amyloid beta plaques associated with Alzheimer's disease (Bao et al., 2016). Conversely, acetylation of TFEB at K91, K103, K116 and K430 was reported to enhance transcription of CLEAR network genes (J. Zhang et al., 2018). These residues may be modulated by acetyl-Coenzyme A acetyltransferase 1 and histone deacetylase (J. Zhang et al., 2018).

Together, TFEB activation appears to be a global adaptation response to cellular stress and a viable option to combat a variety of diseases. The current list of TFEB regulators and TFEB-dependent pathways is unlikely exhaustive. Here, we explore two possible pathways that may depend on TFEB activation. In section 1.2, we explore the role of TFEB in lysosome size dysregulation due to loss of a lysosomal lipid. In section 1.3, we examine the contribution of TFEB on immunoglobulin G-mediated phagocytosis.

1.2 Regulation of lysosome morphology by phosphatidylinositol 3,5-bisphosphate

     Lysosomes are highly heterogenous organelles. Their subcellular position can change, altering their pH and degradative capacity (Johnson, Ostrowski, Jaumouillé, & Grinstein, 2016). While lysosome number may reach into the hundreds in mammalian cells, other species like *Saccharomyces cerevisiae* often have a single, multilobed vacuole (D Sbrissa, Ikonomov, & Shisheva, 1999). Neutrophils have multiple lysosome-related organelles, each with specialized function (Cowland & Borregaard, 2016). Lysosomes are also highly adaptive and can respond to their environment. Immune stimuli are sensed by dendritic cells, inducing reorganisation of spherical lysosomes into a vast tubular network (Mrakovic, Kay, Furuya, Brumell, & Botelho, 2012). Evidently, lysosomes require exquisite regulation to ensure form and function. The number and size of lysosomes remain relatively constant in any given cell type under basal conditions. This is despite extracellular materials and newly synthesized proteins constantly being delivered towards the lysosome by vesicular traffic, driven by the endocytic pathway and biosynthetic pathway from the trans-Golgi network.

1.2.1 Endocytic pathway

     Solutes may be captured from the extracellular milieu including cofactors like iron or growth factors like epidermal growth factor. Capture of these solutes can be facilitated by specific receptors by receptor-mediated endocytosis or non-specifically through pinocytosis. Additionally, invagination of the plasma membrane can be mediated by coat proteins like clathrin (Abe, Inoue, Galvez, Klein, & Meyer, 2008). These plasma membrane-derived invaginations pinch and form endocytic vesicles in the cytosol where they fuse with early endosomes. Here, the cargo and their respective receptors are sorted towards divergent paths.

Membrane bound proteins, like receptors, can be recycled and sorted back to the plasma membrane. In contrast, membrane proteins destined for degradation are ubiquitinated and sorted into intraluminal vesicles by the endosomal sorting complexes required for transport (ESCRT) complex (Katzmann, Babst, & Emr, 2001). The early endosomes can also fuse with each other by interacting with early endosome antigen 1 (EEA1) (Christoforidis, McBride, Burgoyne, & Zerial, 1999). Fission of early endosomes sends cargo to their respective destinations throughout the cell.

As the endosome matures towards the lysosome, early endosomal markers are exchanged for late endosomal markers, including exchange of Rab GTPases from Rab5 to Rab7 respectively (described in greater detail below in the context of phagocytosis) (Rink, Ghigo, Kalaidzidis, & Zerial, 2005). The homotypic fusion and vacuole protein sorting (HOPS) complex facilitates homotypic fusion between Rab7 positive vesicles including late endosomes and lysosomes (Seals, Eitzen, Margolis, Wickner, & Price, 2000). The resulting endolysosome facilitates the degradation of internalized solutes and formed intraluminal vesicles by the various hydrolases. While fusion with the lysosome is often discussed as the final trafficking step in the pathway, mounting evidence supports the recycling of "pure" lysosomes from hybrid endolysosomal degradative compartments (Bissig, Hurbain, Raposo, & van Niel, 2017; Bright, Davis, & Luzio, 2016; Krishna et al., 2016). Compared to the degradative endolysosomes, "pure" lysosomes may be hydrolytically inactive and may serve as terminal storage lysosomes that recapture and concentrate hydrolases for further rounds of fusion and degradation (Bissig et al., 2017; Bright et al., 2016). How endolysosomes are resolved remains relatively unknown.

13

1.2.2 Biosynthetic pathway and recycling pathways

Newly synthesized materials are made by the ribosomes in the endoplasmic reticulum and further processed in the Golgi. Many luminal proteins are modified with glycan chains that feature a mannose 6-phosphate which is targeted for delivery by the mannose 6-phosphate receptor (Braulke & Bonifacino, 2009). These cargos exit the trans-Golgi network and fuse with the early endosome. The mild acidity of the early endosome induces disassociation of the cargo from the receptor. Similar to the endocytic pathway, the cargo and receptor can have divergent paths; the cargo can progress through the endocytic pathway towards the lysosome while the receptor can be recycled back to the trans-Golgi network for further rounds of trafficking. Recycling is mediated by the retromer complex, a pentameric complex composed of two subcomplexes. The vacuolar protein sorting (Vps) trimer of Vps35, Vps29 and Vps26 mediate cargo selection, while the SNX-BAR dimer of SNX1/2 and SNX 5/6 facilitate membrane bending (Carlton et al., 2004; Seaman, McCaffery, & Emr, 1998; Wassmer et al., 2006).

Alternatively, membrane proteins are sorted to the lysosome based on the presence of sorting signals in their cytosolic tails. These sorting signals interact with clathrin adaptor proteins, recruiting the coat protein and inducing vesicle formation (Dietrich, Kastrup, Nielsen, Ødum, & Geisler, 1997; Ohno et al., 1995). These vesicles can either be transported to the plasma membrane and trafficked through the endocytic pathway to reach the lysosome, or be transported directly to endosomes or the lysosome (Mathews, Martinie, & Fambrough, 1992). Despite the numerous trafficking pathways throughout the cell, organelles appear to maintain their identity and accurately target delivery of cargo. A key determinant in maintaining membrane identity are the phosphoinositides.

1.2.3 Phosphoinositides

Phosphoinositides (PtdInsPs) are low abundance membrane lipids involved in numerous cellular functions, including signal transduction, membrane trafficking, and cell motility (Balla, 2013). Existing on the cytosolic leaflet of cellular membranes, phosphatidylinositol (PtdIns) and its phosphorylated derivatives (PtdInsP) constitute 10-20% of all phospholipids. Structurally, PtdInsPs feature a glycerol backbone attached to two fatty acid tails and a *myo*-inositol headgroup (Figure 1.2.1A). The most common fatty acid tail combination is *1-stearyol*-2-*aracadonl*, 38 carbons long with 4 double bonds combined, accounting for 35-75% of PtdIns/Ps in primary mammalian cells (Hicks, DeLong, Thomas, Samuel, & Cui, 2006; Milne, Ivanova, DeCamp, Hsueh, & Brown, 2005). Other fatty acid tails with varying chain lengths and/or degrees of unsaturation can also exist, conferring molecular heterogeneity to PtdIns/P that may influence effector binding (Bone et al., 2017; Schmid, Wise, Mitchell, Nussbaum, & Woscholski, 2004; Shulga, Anderson, Topham, & Epand, 2012).

Meanwhile, most research focuses on functional differences in inositol headgroup phosphorylation. In mammalian cells, reversible phosphorylation at the 3, 4, or 5 position can yield three mono- [PtdIns(3)P, PtdIns(4)P, PtdIns(5)P], three bis- [PtdIns(3,4)P_2, PtdIns(3,5)P_2, PtdIns(4,5)P_2] and one tris-phosphorylated species [PtdIns(3,4,5)P_3]. By comparison, only PtdIns(3)P, PtdIns(4)P, PtdIns(3,5)P_2 and PtdIns(4,5)P_2 are detected in the budding yeast *Saccharomyces cerevisiae*. The conversion between PtdInsP species is mediated by 19 kinases and 28 phosphatases. These enzymes are grouped based on substrate specificity and structural domains, encompassing 8 classes of kinases and 10 classes of phosphatases in mammals (Sasaki et al., 2009).

Each PtdInsP localizes to multiple organelles and recruits specific effectors (Figure 1.2.1B). Some PtdInsPs are concentrated at specific organelles to facilitate basal function. For example, PtdIns(4,5)P_2 regulates clathrin-mediated endocytosis at the plasma membrane (Abe et al., 2008), PtdIns(4)P is found at the trans-Golgi network regulating trans-Golgi network-to-endosome traffic (Y. J. Wang et al., 2003), and PtdIns(3)P controls endosome fusion at the early endosome (Lawe et al., 2002). However, many PtdInsPs are transiently generated in response to various stimuli and appear on alternative organelles. For instance, PtdIns(4)P may also be found at late endosomes and autophagosomes, coordinating endosomal trafficking to the lysosome and autophagosome-lysosome fusion (Craige, Salazar, & Faundez, 2008; Jovic et al., 2012; Minogue, 2006; H. Wang et al., 2015).

These PtdInsPs act as membrane markers, recruiting specific subsets of effectors which often contain PtdInsP binding domains (Hammond & Balla, 2015). To elicit different effects, PtdInsPs found at different membranes rely on coincidence detection. For example, PtdIns(3)P can recruit multiple effectors including EEA1 or Vps5 and Vps17. EEA1 shows specificity for early endosomes, binding to PtdIns(3)P via the FYVE (Fab1, YOTB, Vac1, EEA1) domain (Mu et al., 1995; Stenmark, Aasland, Toh, & D'Arrigo, 1996). Interaction with PtdIns(3)P is insufficient for EEA1 function; the small GTPase Rab5 is also required for EEA1-mediated fusion of early endosomes (Lawe et al., 2002). In contrast, retrograde trafficking in yeast requires PtdIns(3)P dependent recruitment of retromer subunits Vps5 and Vps17 (Horazdovsky et al., 1997; Seaman et al., 1998). These proteins have a Phox homology (PX) domain that has low affinity for PtdIns(3)P individually (Horazdovsky et al., 1997). However, dimerized Vps5 and Vps17 have greater avidity for PtdIns(3)P and are recruited to the retromer trimer subcomplex to facilitate retrograde traffic from the endosomes (Seaman et al., 1998; Yu & Lemmon, 2001).

Thus, PtdInsPs can confer organelles with an identity and is intimately involved in regulating organelle function.

1.2.4 Phosphatidylinositol 3,5-bisphosphate

Lysosomes and late endosomes, in particular, are enriched with PtdIns(3,5)P_2. The primary route of PtdIns(3,5)P_2 synthesis relies on the lipid kinase PIKfyve (Fab1 in yeast) (Figure 1.2.2) (Gary, Wurmser, Bonangelino, Weisman, & Emr, 1998; Sbrissa, Ikonomov, & Shisheva, 2002). Its precursor, PtdIns(3)P, is generated at the endosome by the Vps34 (Ikonomov et al., 2015; Schu et al., 1993). In turn, PtdIns(3)P is recognized by PIKfyve via its FYVE domain, and phosphorylates the inositol ring at the 5-position to yield PtdIns(3,5)P_2 (Burd & Emr, 1998; Ikonomov et al., 2015). Interestingly, PIKfyve forms a complex with its antagonizing phosphatase Sac3 (Fig4 in yeast), scaffolded by multiple copies of ArPIKfyve (Vac14 in yeast) (Alghamdi et al., 2013; Botelho, Efe, Teis, & Emr, 2008; Gary et al., 2002; Natsuko Jin et al., 2008; Rudge, 2003; Sbrissa, Ikonomov, Fenner, & Shisheva, 2008). Importantly, formation of the complete complex is necessary for PIKfyve activity; disruption to ArPIKfyve or Sac3 reduce PtdIns(3,5)P_2 levels, suggesting ArPIKfyve and Sac3 play positive regulatory functions on PIKfyve. In yeast, the Fab1 complex also includes Vac7 and Atg18, which positively and negatively regulate Fab1 function respectively (Dove et al., 2004; Natsuko Jin et al., 2008; Poirier, Eroglu, & Marko, 2002). Alternatively, PtdIns(3,5)P_2 can be dephosphorylated by myotubularin-related (MTMR) 3-phosphatases to form PtdIns(5)P (Shen et al., 2009; D. M. Walker et al., 2001; Zolov et al., 2012). Regulation of PtdIns(3,5)P_2 synthesis is highly regulated and is required for proper cellular function.

At an organism level, PtdIns(3,5)P_2 synthesis appears to be required for development. PIKfyve knockout lead to embryonic lethality (Ikonomov et al., 2011). Defective PtdIns(3,5)P_2 synthesis, induced by disrupting other components of the PIKfyve complex in mouse models, lead to reduced lifespan, neurological degeneration, insufficient myelination of axons and reduced coat colour (C. J. Ferguson et al., 2012; Lenk et al., 2016; Liggins et al., 2018). At a cellular level, defective PtdIns(3,5)P_2 synthesis abrogates certain trafficking pathways, lysosomal ion regulation, transcriptional regulation, and signaling at the lysosome.

One trafficking pathway dysregulated by the loss of PtdIns(3,5)P_2 is autophagy, the lysosome-dependent degradation of organelles or protein complexes. These materials are packaged into double membrane organelles known as autophagosomes that fuse with the lysosome. LC3-II is recruited to the autophagosomal membrane and is digested by the lysosome with the cargo of the autophagosome (Kabeya, 2000). Depletion of PtdIns(3,5)P_2 by pharmacological inhibition of PIKfyve or in mutant primary mouse neuronal cells lead to an accumulation of autophagic markers including LC3-II (de Lartigue et al., 2009; Cole J. Ferguson, Lenk, & Meisler, 2009; S. M. Kim et al., 2016). Furthermore, impairment of cargo degradation lead to a significant increase in LC3-II levels relative to PIKfyve inhibition alone (de Lartigue et al., 2009). Together, these results implicate PIKfyve in autophagosome degradation.

Lysosomal ion homeostasis is also regulated by PtdIns(3,5)P_2. Specifically, the Ca^{2+}, Na^+, and K^+ channels appear to be regulated by PtdIns(3,5)P_2. The Ca^{2+} channel transient receptor potential ion channels mucolipin-1 (TRPML1) was shown to directly bind to PtdIns(3,5)P_2 via amino acids 1-69 of the N-terminal tail (Dong et al., 2010). Binding of TRPML1 by PtdIns(3,5)P_2 induced Ca^{2+} flux into the cytosol. Similarly, the Na^+-selective two

pore channel 1 and 2 (TPC1 & TPC2) can also be activated by PtdIns(3,5)P_2 (X. Wang et al., 2012). In yeast, the K^+/H^+ antiporter Vnx1 is also positively regulated by PtdIns(3,5)P_2 (Wilson, Scott, Dowell, & Odorizzi, 2018). Assembly and activity of the V-ATPase was also suggested to be promoted by the presence of PtdIns(3,5)P_2, suggesting a role in acidification of the lysosome (S. C. Li et al., 2014). While others have suggested that lysosomes become basified (Dove et al., 2002; Jefferies et al., 2008), several groups showed that the yeast vacuole and mammalian lysosomes were not impaired when PtdIns(3,5)P_2 is lost (Ho, Choy, Wattson, Johnson, & Botelho, 2015; Krishna et al., 2016; Wilson et al., 2018).

PtdIns(3,5)P_2 is also involved in transcriptional regulation in yeast. Tup1 and Cyc8 play dual roles in transcriptional repression and activation of over 150 genes, including the GAL1 gene in galactose metabolism (Han & Emr, 2011). Here, the presence of glucose restricts galactose metabolism. Tup1-Cyc8 bind to promoters and recruit transcriptional repressors such as the DNA binding protein Mig1. When carbon sources shift, GAL1 gene is activated to promote galactose metabolism. PtdIns(3,5)P_2 at the vacuole recruits the repressive Tup1-Cyc8 complex and Cti6, facilitating their interaction. When associated with Cti6, Tup-Cyc8-Cti6 is a transcriptional activator and recruits other transcriptional activators like SAGA to promote activation of the same genes it previously suppressed (Han & Emr, 2011). This conversion has been termed PtdIns(3,5)P_2 dependent Tup1 conversion (PIPTC).

mTORC1 recruitment and activation may also be influenced by PtdIns(3,5)P_2 (Bridges et al., 2012; N. Jin et al., 2014). Adipocytes generate PtdIns(3,5)P_2 at the plasma membrane in response to insulin signaling, in a PI3-kinase class IIα (PI3KC2α) dependent manner (Bridges et al., 2012). Recruitment of mTORC1 is mediated by direct interaction between PtdIns(3,5)P_2 and the WD40 domain of Raptor. This phenomenon is also observed in yeast, where TORC1 is

recruited to the vacuole instead of the plasma membrane (N. Jin et al., 2014). Interestingly,

PtdIns(3,5)P_2 also recruited substrates of TORC1, including the S6K yeast homolog Sch9.

1.2.6 PtdIns(3,5)P_2 modulates lysosome size

The most obvious phenotype from changes to PtdIns(3,5)P_2 levels is the modulation of

lysosome size. Changes in lysosome size appear to be inversely correlated to the amount of

PtdIns(3,5)P_2 in the cell. Perturbations to the PIKfyve/Fab1 complex lead to reduced

PtdIns(3,5)P_2 levels and have swollen lysosomes (Rutherford, 2006; Yamamoto et al., 1995).

The striking enlargement of lysosome size has been linked to several defects including lysosomal

osmotic balance, retrograde traffic, intraluminal vesicle formation, and lysosome reformation.

Several lines of evidence suggest osmotic regulation is necessary for maintaining

lysosome size. Strikingly, hyperosmotic shock increased PtdIns(3,5)P_2 levels 20-fold in yeast,

inducing vacuole fragmentation (Dove et al., 1997). The fragmentation of the vacuole was

suggested to maintain cytosolic osmolarity by expelling water from the vacuole (Efe, Botelho, &

Emr, 2005). Furthermore, lysosome enlargement from PIKfyve inhibition can be abated by

changes to various ion channels. Overexpression of TRPML1 or knockout of the subunits for a

Cl$^-$/H$^+$ exchanger, CLCN7 or OSTM1, abated lysosome enlargement during in $fig4^{-/-}$ or PIKfyve

inhibited cells respectively (Dong et al., 2010; Gayle et al., 2017). Similarly, loss of function of

the yeast K$^+$/H$^+$ antiporter Vxn1 or V-ATPase subunit Vph1 also blocked lysosome enlargement

during $fab1\Delta$ (Wilson et al., 2018). Some of these channels may be necessary for pH regulation

of the lysosome. Indeed, inhibition of the V-ATPase during PIKfyve inhibition can also block

lysosome enlargement (Saveanu & Lotersztajn, 2016; Schulze et al., 2017; Wilson et al., 2018).

Proper membrane traffic is also necessary to maintain lysosome size. While endosomal trafficking to the lysosome and biosynthetic traffic from the Golgi to the lysosome appears normal, impaired retrograde traffic and MVB formation may contribute excess membrane that leads to lysosomal enlargement. (Bryant, Piper, Weisman, & Stevens, 1998; Dove et al., 2002, 2004; Odorizzi, Babst, & Emr, 1998; Rutherford, 2006). Retrograde traffic allows for recycling of receptors that deliver lysosome luminal components. In yeast, delivery of the hydrolase alkaline phosphatase bypasses the endosome-like prevacuolar compartment (PVC) to reach the vacuole directly and is retained on the vacuolar membrane. By fusing a retention sequence for recycling back to the trans-Golgi network, retention sequence alkaline phosphatase continues to traffic directly to the vacuole but is continuously retrieved from the vacuole and appears in the Golgi. Interestingly, mutation to vac7 induced accumulation of retention sequence ALP on the vacuolar membrane suggesting defects in recycling (Bryant et al., 1998). In mammalian cells, localization of cation independent mannose 6-phosphate receptor accumulated at the early endosome in PIKfyve knockdown cells, suggesting a failure in recycling to the trans-Golgi network (Rutherford, 2006).

A candidate protein regulating recycling is the Rab9 effector p40, which is necessary for retrograde traffic of the cation independent mannose 6-phosphate receptor (Ikonomov et al., 2003). Here, p40 was suggested to be phosphorylated by PIKfyve and interacts with Rab9 to promote retrograde traffic. Another key regulator of lysosome fission in yeast is Atg18. *atg18Δ* yeast have enlarged lysosomes while paradoxically having 5-10 times more PtdIns(3,5)P_2 compared to their wild type counterparts which persists even during hyperosmotic shock (Dove et al., 2004). Atg18 was suggested to be involved in membrane scission by the presence of an unstructured hydrophobic loop that folds into an α-helix upon lipid binding (Gopaldass, Fauvet,

Lashuel, Roux, & Mayer, 2017). This α-helix can insert into the membrane to promote

membrane deformation. PtdIns(3,5)P_2 is necessary for oligomerization of Atg18, leading to

tubulation of the membrane and subsequent membrane fission (Gopaldass et al., 2017; Scacioc et

al., 2017). In mammalian cells, Atg18 has 4 homologs, the WD40 repeat protein interacting with

phosphoinositides (WIPI) 1 through 4 (WIPI1-WIPI4) (Proikas-Cezanne, Takacs, Donnes, &

Kohlbacher, 2015). However, they have not been implicated in regulation of lysosome size

(Krishna et al., 2016). Without the removal of membrane intended for retrograde traffic, the

lysosomes appear to inherit the extra membrane contributing to lysosome enlargement.

MVB formation may also be impaired, leading to lysosome enlargement. Some

hydrolases are expressed as transmembrane proteins and sorted into intraluminal vesicles by the

ESCRT complex. Degradation of the vesicle liberates the hydrolase, allowing it to fill the

vacuole. Using the polyphosphate phosphatase PHM5 as a model, Dove et al showed that PHM5

in *vac7Δ* and *vac14Δ* yeast was restricted to the limiting membrane of the vacuole, suggesting

MVB formation was impaired (Dove et al., 2002). Similar defects can be seen tracking

carboxypeptidase S (CPS) (Odorizzi et al., 1998). Without the ability to form intraluminal

vesicles, membrane intended for degradation could contribute to lysosome enlargement.

Another possible reason for lysosome enlargement may be the inability for lysosomes to

reform. Upon fusion with phagosomes and autophagosomes, lysosomes are reformed by various

mechanisms, including budding and vesicle formation. Recent evidence suggests lysosomes are

unable to reform when PIKfyve is inhibited (Bissig et al., 2017; Krishna et al., 2016). This

failure to fission prevents endolysosomes from shrinking and may be a contributing factor to the

swelling of lysosomes.

1.2.7 Rationale and hypothesis

While the current understanding focuses on defects in membrane trafficking, the emergence of TFEB as a master regulator of lysosome biogenesis has yet to be considered. Two lines of evidence support a potential role for TFEB. First, TFEB activation by overexpression alone can increase lysosome number. Additionally, $PtdIns(3,5)P_2$ may indirectly modulate TFEB function through modulating mTORC1 activity (Bridges et al., 2012; N. Jin et al., 2014). In basal cells, $PtdIns(3,5)P_2$ is present and can activate mTORC1. In turn, mTORC1 suppresses TFEB function and lysosome biogenesis is off. Conversely, if PIKfyve is inhibited and $PtdIns(3,5)P_2$ levels decrease, mTORC1 can become less active promoting TFEB activity. Therefore, we hypothesize that $PtdIns(3,5)P_2$ can modulate TFEB nuclear localization may altering mTORC1 function. The resulting vacuolation phenotype may be enhanced by TFEB-mediated lysosome biogenesis.

To test this, we focus on three main objectives:

1) To determine whether TFEB and family members become active during PIKfyve inhibition;

2) To determine the signaling requirements for TFEB activation,

3) To quantify the relative contribution of TFEB on PIKfyve-induced lysosome enlargement.

1.3 The regulation of lysosome biogenesis in phagocytosis

Phagocytosis is the actin-dependent engulfment of particles greater than 0.5 µm in size.

Unicellular eukaryotes, like the amoeba *Dictyostelium*, rely on phagocytosis to engulf bacteria as

a food source (Cosson & Soldati, 2008). In contrast, higher eukaryotes can employ phagocytosis

for tissue maintenance. Various cell types, including epithelial cells, can phagocytose

neighbouring apoptotic cells (Monks et al., 2005). Phagocytosis is also necessary for the immune

system. Professional phagocytes, like macrophages, survey their environment and engulf any

potential pathogens they encounter (Rabinovitch, 1995).

The recognition of various particles is mediated by interaction of specific receptors with

ligands displayed on the surface of the particle. Phagocytes express many pattern recognition

receptors (PRR) that collectively target conserved components of the pathogen, known as

pathogen-associated molecular patterns (PAMP). For example, Gram negative bacteria can be

targeted by the presence of cell wall component lipopolysaccharide (LPS). Recognition of LPS

by scavenger receptor class A mediates phagocytosis of the bacteria (Peiser et al., 2002).

Alternatively, phagocytes can recognize their prey through indirect means. Host-derived

opsonins, including immunoglobulins and complement proteins, can bind to the pathogen and are

recognized by a common set of receptors. Of the two, immunoglobulins target specific ligands

on the pathogen. Immunoglobulins can be subdivided into five classes, with immunoglobulin G

(IgG) representing the most abundant form (Vidarsson, Dekkers, & Rispens, 2014).

1.3.1 Immunoglobulin G

The best characterized opsonin-receptor pair is immunoglobulin G (IgG) and its

corresponding Fcγ receptor. IgG is a tetrameric protein consisting of two identical light chains

and two identical heavy chains (Figure 1.3.1) (Gore, Andersson, Biran, Underwood, & Riesenfeld, 2014). Each light chain consists of one variable region (VL) and one constant region (CL), while each heavy chain is composed of one variable region (VH) and three constant regions (CH1, CH2, and CH3). The resulting IgG molecule adopts a Y shape, with two fragment antigen binding (Fab) regions and one fragment constant (Fc) region. Each Fab region contains the variable region of one heavy chain and one light chain and the following constant region (VL-CL and VH-CH1). Together, these variable regions are responsible for binding of unique antigens. IgG can be subdivided into four subclasses in humans (IgG1, IgG2, IgG3, IgG4) and in mice (IgG1, IgG2a IgG2b IgG3). Major differences in the amino terminal CH2 domain and linker region between CH1 and CH2 can alter immune functions, such as complement or Fcγ receptor binding (Canfield, 1991; Garred, Michaelsen, & Aase, 1989). The Fc region, defined by the two CH2-CH3 regions of the heavy chain, is responsible for Fcγ receptor binding. In addition, the presence of an N-linked glycan at Asn297 of the CH2 domain is required for Fcγ receptor binding (M. R. Walker, Lund, Thompson, & Jefferis, 1989).

1.3.2 Fcγ receptors

The Fcγ receptors are similarly diverse. Humans have three classes of FcγR subdivided into FcγRI, FcγRIIA, FcγRIIB, FcγRIIC, FcγRIIIA, and FcγRIIIB. Meanwhile, mice have four classes of FcγR, composed of FcγRI, FcγRIIB, FcγRIII, FcγRIV. These FcγR can be further classified based on whether they activate or inhibit signaling from the receptor. Receptors that activate signaling contain an immunoreceptor tyrosine-based activation motif (ITAM), characterized by tandem YxxI/L motifs. Meanwhile, inhibitory signals are mediated by the presence of an immunoreceptor tyrosine-based inhibition motif (ITIM). When the ITIM is

activated, inositol and protein phosphatases are recruited and antagonize signaling from the ITAM (discussed further below) (D Cox, Dale, Kashiwada, Helgason, & Greenberg, 2001; Joshi, Singh, Zulcic, & Durden, 2014). The only receptor containing the inhibitory ITIM is FcγRIIB in both human and mouse. Therefore, relative expression of these receptors will dictate the types of responses from immune cells.

Of the receptors that activate signaling, only FcγRI has high affinity for IgG while all others have lower affinity. Thus, engagement of the particle with a single FcγR is unable to maintain ligand-receptor binding. Phagocytes actively probe their environment with actin-rich membrane ruffles and filopodia to aide engagement of multiple receptors with an opsonized particle (Flannagan, Harrison, Yip, Jaqaman, & Grinstein, 2010). Engagement of a multivalent prey allows receptor clustering and initiation of downstream signaling starting with phosphorylation of ITAM domains (Sobota et al., 2005) (Figure 1.3.2). Phosphorylation of the tandem ITAMs is mediated by Src family kinases (Ghazizadeh, Bolen, & Fleit, 1994; Hamada, Aoki, Akiyama, & Toyoshima, 1993; Ibarrola et al., 1997; Suzuki et al., 2000). In turn, phospho-ITAMs serve as a docking site for spleen tyrosine kinase (Syk) via interaction with Src homology 2 (SH2) binding domain (Johnson et al., 1995). Integrins form diffusion barriers around the phagocytic cup that block phosphatases like CD45 from dephosphorylating the ITAM and dampening the signal (Freeman et al., 2016). Activation of Syk leads to the recruitment of specific downstream activators or adaptor proteins. The linker of activated T cells (LAT), an adaptor, is recruited to activated Syk and is responsible for recruitment of PLCγ and another adaptor, Grb2 (Tridandapani et al., 2000). Grb2 further recruits Gab2, which along with Syk recruit class I PI3K (PI3KCI) to generate PtdIns(3,4,5)P_3 (Gu, Botelho, Yu, Grinstein, & Neel,

2003). Recruitment of PLCγ and PI3KCI illustrate the importance of phosphoinositide signaling during phagocytosis.

1.3.3 Phosphoinositide dynamics during phagocytosis

PtdInsPs at the plasma membrane play significant roles for the coordination of actin polymerization during phagocytosis. Coordination of PtdIns(4,5)P_2 and PtdIns(3,4,5)P_3 levels promote actin assembly and disassembly at specific times during the internalization process. Upon Fcγ receptor engagement, PtdIns(4,5)P_2 levels appear to increase through recruitment of the PtdIns(4)P 5-kinase PIPKIα (Botelho et al., 2000; Mao et al., 2009). To further support synthesis of PtdIns(4,5)P_2, PLD is necessary for phagocytosis and appears to recruit and activate PIP5K (Divecha et al., 2000; Kusner, Hall, & Jackson, 1999). Local synthesis of PtdIns(4,5)P_2 induces actin polymerization and pseudopod extension around the particle (Scott et al., 2005). As pseudopods extend, PtdIns(4,5)P_2 synthesis follows pseudopod extension, with a concurrent loss of PtdIns(4,5)P_2 at the base of the phagocytic cup (Scott et al., 2005). Loss of PtdIns(4,5)P_2 and actin disassembly is required for phagosome closure (Fairn et al., 2009; Scott et al., 2005) and appears to be dependent on the recruitment of phospholipase Cγ (PLCγ) to LAT (Tridandapani et al., 2000).

Alternatively, PtdIns(4,5)P_2 can also be turned over into PtdIns(3,4,5)P_3. Recruitment of the regulatory subunit of PI3KCI, p85, is mediated by SH2 interaction with Syk and Gab2 (Gu et al., 2003; Moon et al., 2005). Not only does PI3KCI deplete PtdIns(4,5)P_2 from the phagocytic cup, PtdIns(3,4,5)P_3 also appears to be necessary for phagocytosis, particularly for larger particles (Schlam et al., 2015; Vieira et al., 2001). One possibility is that PtdIns(3,4,5)P_3 recruits myosin X, which may be necessary for phagosome closure (Dianne Cox et al., 2002).

Furthermore, the spatiotemporal generation of PtdIns(4,5)P_2 or PtdIns(3,4,5)P_3 are necessary to regulate the Rho GTPases at distinct stages of internalization.

1.3.4 Actin polymerization via Rho GTPases

Key molecular switches that control actin dynamics are the Rho GTPases. These small GTPases are part of a larger superfamily of Ras GTPases, that include the Rab GTPases necessary for membrane trafficking (described below) and Rag GTPases involved in recruitment of mTORC1 and TFEB to the lysosome. Typically, these GTPases switch between an inactive GDP-bound form and an active GTP-bound form. One of the exceptions Rag C/D that is considered active when bound to GDP. Nevertheless, GDP-bound GTPases are considered off due to their inability to bind to effector proteins. While GDP-bound, some GTPases can interact with guanine dissociation inhibitors (GDI), which inhibits activation by GEFs and may mask the membrane-anchoring prenyl group (Dransart, Morin, Cherfils, & Olofsson, 2005). To become active, GDP is removed by guanine nucleotide exchange factors (GEFs) and replaced with GTP. GTPases with prenyl groups may be deposited into their target membranes. There, the active GTPase is now in a conformation that allow binding to effectors. Although GTPases have hydrolytic activity towards GTP, their enzymatic activity is slow and inefficient. GTPase activating proteins (GAPs) help to induce hydrolysis of the γ-phosphate of GTP, returning the GTPase to an inactive state.

The GTPases involved in actin polymerization during Fcγ receptor-mediated phagocytosis include those of the Rho family: Cdc42, Rac1 and Rac2. Cdc42 is activated first to initiate actin polymerization, with Rac1 following shortly thereafter and then Rac2 (Hoppe, 2004). Interestingly, Rac2 only becomes active at the phagocytic cup (Hoppe, 2004). Activation

of Cdc42 depends on recruitment of the adaptor Nck, which can be phosphorylated by Src family

kinases (Dart, Donnelly, Holden, Way, & Caron, 2012). This in turn recruits the Cdc42 GEF

intersectin-1, Cdc42 itself, and nucleation promotion factor (NPF) Wiskott–Aldrich Syndrome

protein (WASp) to promote actin polymerization (Humphries, Donnelly, & Way, 2014).

Additionally, WASp is stabilized at the plasma membrane by the presence of PtdIns(4,5)P_2

(Higgs & Pollard, 2000; Pauker et al., 2014). In contrast, activation of Rac1/2 is thought to be

mediated by the GEFs Dock180-ELMO and Vav. Activated ITAMs recruit the adaptor protein

CrkII, which in turn recruits the Rac-GEF Dock180-ELMO (Lee, Cosio, Ireton, & Grinstein,

2007). On the other hand, Vav may be directly activated by Syk (Deckert, Tartare-Deckert,

Couture, Mustelin, & Altman, 1996; Hall et al., 2006). Rac1, together with PtdIns(4,5)P_2 and

Nck1, can activate N-WASp to promote actin polymerization (Tomasevic et al., 2007).

Together, activated WASp and N-WASp interact with the Arp2/3 complex, which leads

to branched-actin polymerization (May, Caron, Hall, & Machesky, 2000). Arp2/3 is a seven-

subunit complex, featuring the actin-like Arp2 and Arp3. Activation of WASp by Rho-GTPases

relives autoinhibition exposing two domains necessary for actin assembly (A. S. Kim, Kakalis,

Abdul-Manan, Liu, & Rosen, 2000). The C-terminal VCA domain of WASp interacts with

Arp2/3, inducing a conformational change, while the N-terminal Wiskott-Aldrich syndrome

protein homology 2 (WH-2) domain binds and delivers actin to Arp2/3 (Machesky & Insall,

1998). Together, Arp2/3 and the G-actin monomer form a trimer that can nucleate actin

polymerization from an existing actin filament. As actin polymerizes and pushes the plasma

membrane, additional Fcγ receptors engage the particle and promote zippering of the plasma

membrane around the particle (Swanson & Baer, 1995).

As described above, phagosome closure requires actin depolymerization and PtdIns(4,5)P_2 turnover. PtdIns(4,5)P_2 must be depleted from the membrane to stop Cdc42 and Rac1-mediated WASp/N-WASp activation. PtdIns(4,5)P_2 can be turned over by PLCγ, which forms diacylglycerol (DAG) and inositol trisphosphate (IP$_3$) (Tridandapani et al., 2000). Alternatively, PtdIns(3,4,5)P_3 generation by PI3KCI is required to recruit GAPs for Cdc42 and Rac1 (Schlam et al., 2015). As PtdIns(4,5)P_2 is consumed and Rho GTPases are deactivated, actin depolymerizes from the phagocytic cup. Subsequent closure of the phagosome may be mediated by myosin X (Dianne Cox et al., 2002).

1.3.5 Phagosome maturation

Immediately following phagocytic cup closure, the particle encapsulated in a nascent phagosome that resembles the plasma membrane and extracellular milieu. This phagosome is ill-equipped to digest the particle and must undergo maturation to acquire degradative properties. Phagosome maturation involves step-wise fusion with early endosomes, late endosomes, and lysosomes, a process that largely mirrors the endocytic pathway. Fusion of phagosomes with early endosomes requires the recruitment of the Rab5 GTPase (Vieira et al., 2003). Rab5 recruitment is mediated by the presence of Rab20 at the phagosome, which recruits the Rab5 GEF Rabex-5 (Pei, Repnik, Griffiths, & Gutierrez, 2014). GTP-bound Rab5 enhances its own activation by recruiting Radaptin-5, which activates Rabex-5, promoting a positive-feedback loop to promote Rab5 activity (Stenmark, Vitale, Ullrich, & Zerial, 1995; Z. Zhang et al., 2014). Activated Rab5 recruits additional effectors to promote fusion with the early endosome. A key step is the acquisition of PtdIns(3)P at the phagosome, which depends on indirect recruitment of Vps34 by Rab5. By interacting with p150 of the Vps34 complex, Rab5 recruits the class III

PI3K, enriching the phagosome with PtdIns(3)P. Next, EEA1 interacts with both PtdIns(3)P and

Rab5 to facilitate fusion between early endosomes and phagosomes by coordinating the early

endosomal soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs)

syntaxin-13 and potentially syntaxin-6 (Christoforidis et al., 1999; Collins, Schreiber, Grinstein,

& Trimble, 2002; Lawe et al., 2002; McBride et al., 1999; Simonsen, Gaullier, D'Arrigo, &

Stenmark, 1999).

Further maturation involves Rab switching from Rab5 to Rab7. The Mon1, complexed

with Ccz1, is recruited to GTP-bound Rab5 and has two major functions (Poteryaev, Datta,

Ackema, Zerial, & Spang, 2010). First, Rabex-5 is displaced terminating the positive feedback

loop of Rab5 activation (Poteryaev et al., 2010). Second, Rab7 is recruited to the phagosome

where Mon1-Ccz1 acts as the GEF for Rab7 activation (Cabrera et al., 2014; Kinchen &

Ravichandran, 2010; Nordmann et al., 2010; Yasuda et al., 2016). Rab7 is essential for

phagosome maturation but the proceeding steps leading to lysosome fusion are less clearly

defined (Harrison, Bucci, Vieira, Schroer, & Grinstein, 2003).

Evidence suggests Rab7 is necessary for several roles in maturation. Transport of the

phagosome towards the lysosome is mediated by the microtubules and the minus-end directed

motor protein complex dynein-dynactin (Johansson et al., 2007). Rab7 interacts with the adaptor

Rab7-interacting lysosomal protein and oxysterol-binding protein-related protein 1L, which in

turn interact with dynein-dynactin (Harrison et al., 2003; Johansson et al., 2007). Association

with RILP and dynein-dynactin may also be necessary for phagosome membrane tabulation

towards the lysosome for the direct acquisition of the V-ATPase pump (Harrison et al., 2003;

Sun-Wada, Tabata, Kawamura, Aoyama, & Wada, 2009). Fusion with of the phagosome with

late endosomes may be facilitated by the HOPS complex, which features two Rab7 binding

subunits. Similar to EEA1 above, HOPs may also coordinate SNAREs, including SNAP-23 and syntaxin 7 (Collins et al., 2002; Sakurai et al., 2012).

Another key determinant in phagosome maturation is the turnover of PtdIns(3)P to PtdIns(3,5)P_2. Independently of Rab switching, PtdIns(3)P appears to be synthesized until the pH of the phagosome decreases, inducing Vps34 inactivation and turnover of PtdIns(3)P to PtdIns(3,5)P_2 (Naufer et al., 2018). PtdIns(3,5)P_2, also appears to be necessary for phagosome-lysosome fusion. Disrupting PtdIns(3,5)P_2 synthesis lead to delayed acquisition of lysosomal markers and reduced degradation (G. H. E. Kim, Dayam, Prashar, Terebiznik, & Botelho, 2014). This effect is in part due to reduced activity of the PtdIns(3,5)P_2-gated calcium channel, TRPML1. TRPML1 silencing or chelation of calcium lead to phagosomes docked to lysosomes that were unable to fuse (Dayam, Saric, Shilliday, & Botelho, 2015). Once phagosomes fully fuse with the lysosomes, the particle is fully degraded by the various hydrolases and acidic lumen.

1.3.6 Rationale and hypothesis

Lysosome biogenesis during starvation enhances degradation of autophagosomes to liberate energy to enhance survival (Roczniak-Ferguson et al., 2012). Similarly, phagocytes may use the same strategy in response to pathogens to be degraded. Making more lysosomes may enhance degradation and prepare the immune system for subsequent waves of pathogens. We hypothesize that macrophages challenged with IgG-opsonized latex beads will enhance lysosome biogenesis, priming the cell to be more proteolytic.

To test this, we focus on three main objectives:

1)   To determine if Fcγ receptor engagement is sufficient for TFEB activation;

2) To determine whether Fcγ receptor engagement enhances proteolytic potential of the macrophage;

3) To elucidate the signaling pathway that connects the Fcγ receptor with TFEB.

1.4 Figures
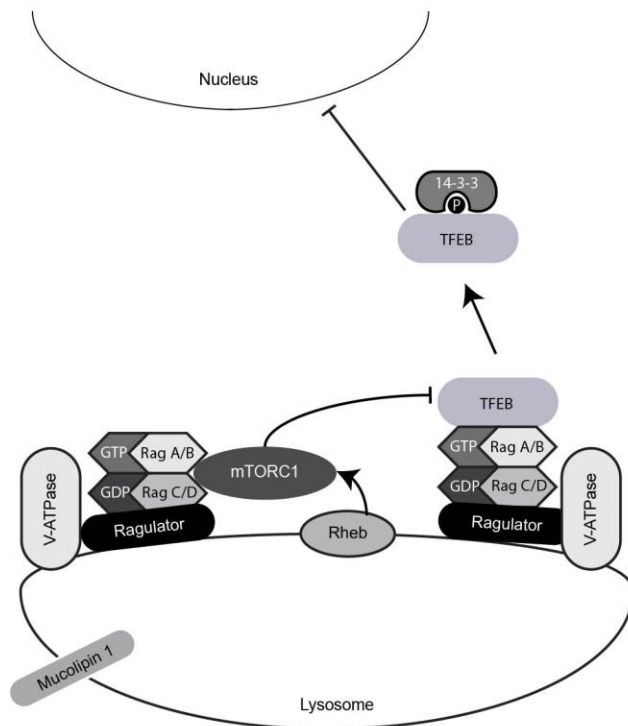

A — Fully fed
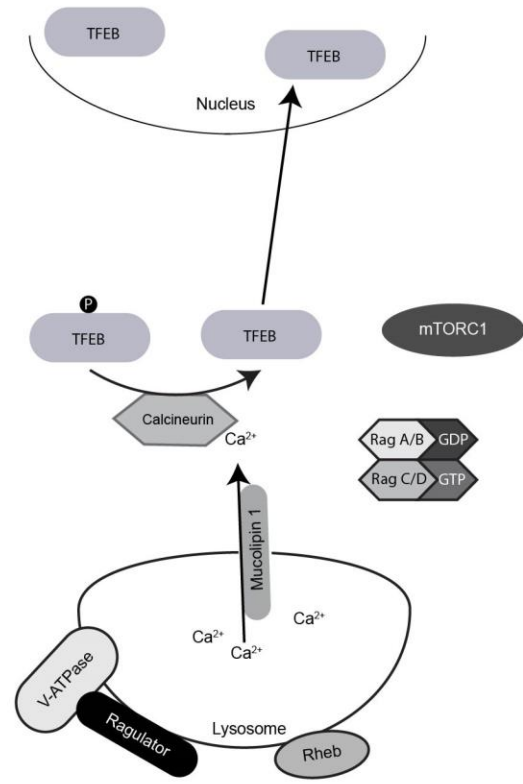

B — Starvation

Figure 1.1.1: TFEB regulation by mTORC1 and nutrients. The best understood regulator of TFEB is mTORC1 in response to nutrients. (A) When amino acids are available, Rag GTPases recruit mTORC1 and TFEB to the lysosomal surface. mTORC1 is further activated by Rheb in response to growth factors, and phosphorylate TFEB on S211, among others. Phosphorylated TFEB associates with 14-3-3, which blocks the nuclear localization sequence, leading to cytosolic sequestration. (B) Under starvation conditions, Rag GTPases are off and mTORC1 is inhibited. Here, the calcium channel mucolipin-1 becomes active and releases lysosomal calcium to promote calcineurin activity. This phosphatase dephosphorylates TFEB at S211, allowing TFEB to enter the nucleus.
Figure 1.1.2: Regulation of TFEB by post-translational modifications. TFEB is known to be phosphorylated by at six kinases and two phosphatases. Many of these phosphates modulate nuclear/cytosolic localization (black circles with P). PKCβ appears to be unique, modulating TFEB stability instead (grey circles with P). TFEB is also known to be modified with SUMO (white circle with S) and acetyl (white circle with A) groups, altering their DNA binding properties. The relative positions and residues are indicated along the protein. Indicated in parentheses is the residue numbering in mouse, if different from human.

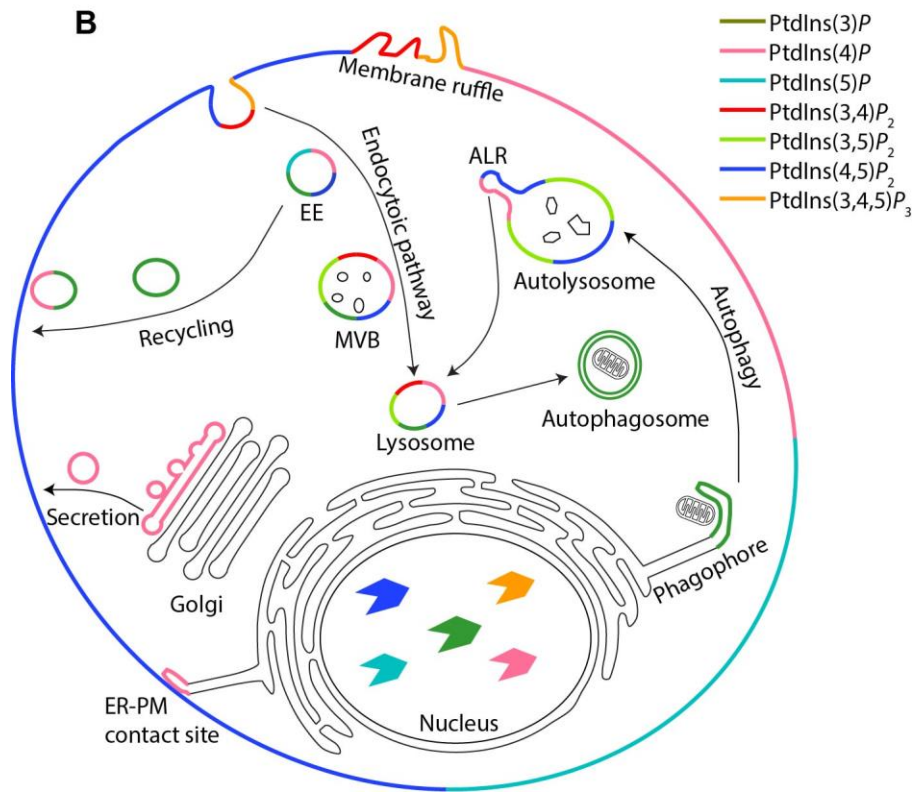

Figure 1.2.1: Phosphatidylinositol structure and localization of its phosphorylated derivatives. (A) Phosphatidylinositol is composed of a glycerol backbone, a *myo*-inositol head group, and two fatty acid tails. These fatty acids are most commonly *1-stearyol*-2-*aracadonl*. Phosphorylation of the headgroup can occur at positions 3 and/or 4 and/or 5, yielding 7 phosphorylated derivatives or PtdInsPs. (B) These PtdInsPs are typically thought to have very narrow localization throughout the cell. However, each organelle typically hosts multiple PtdInsPs, which can be generated in response to a specific stimulus or accumulate to regulate basal function of the organelle. This figure is published in (Choy, Han, & Botelho, 2017).

PtdIns(5)P

Figure 1.2.2: Synthesis and turnover of PtdIns(3,5)P_2. The conversion of PtdInsP is often mediated by numerous kinases and phosphatases. However, PtdIns(3,5)P_2 is thought to be synthesized by a single pathway. Endosomal PtdIns is phosphorylated by Vps34 to generate PtdIns(3)P. This PtdIns(3)P is the primary precursor for PtdIns(3,5)P_2 and is phosphorylated by the PIKfyve kinase. PtdIns(3,5)P_2 can be turned over by the 5-phosphatase Sac3 into PtdIns(3)P, or by 3-phosphatases MTMR to yield PtdIns(5)P.
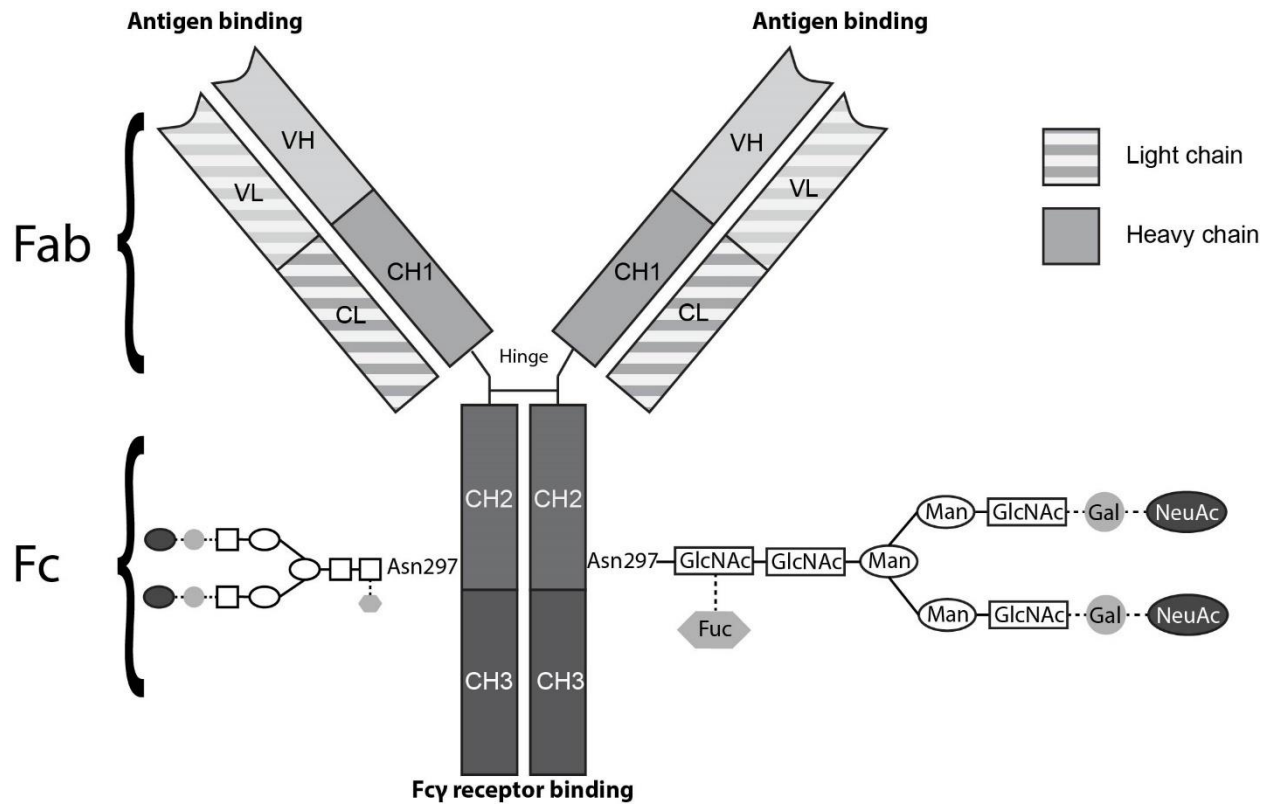

Figure 1.3.1: Basic structure of typical immunoglobulin G. IgG is made up of two heavy chains and two light chains. The heavy chain is made up of 4 regions, one variable region (VH) and three constant regions (CH1-3). Meanwhile, the light chain is made up of two regions, one variable (VL) and one constant (CL) region. The variable regions form heterodimers and facilitate antigen binding (Fab region). In contrast, the CH2-CH3 domains of the two heavy chains dimerize and are responsible for Fcγ receptor binding. A critical feature of the CH2 domain is the presence of a glycan chain at Asn297 that is required for Fcγ receptor binding. Different IgG isoforms often differ in their hinge region and can bind to Fcγ receptor isoforms with different affinities.
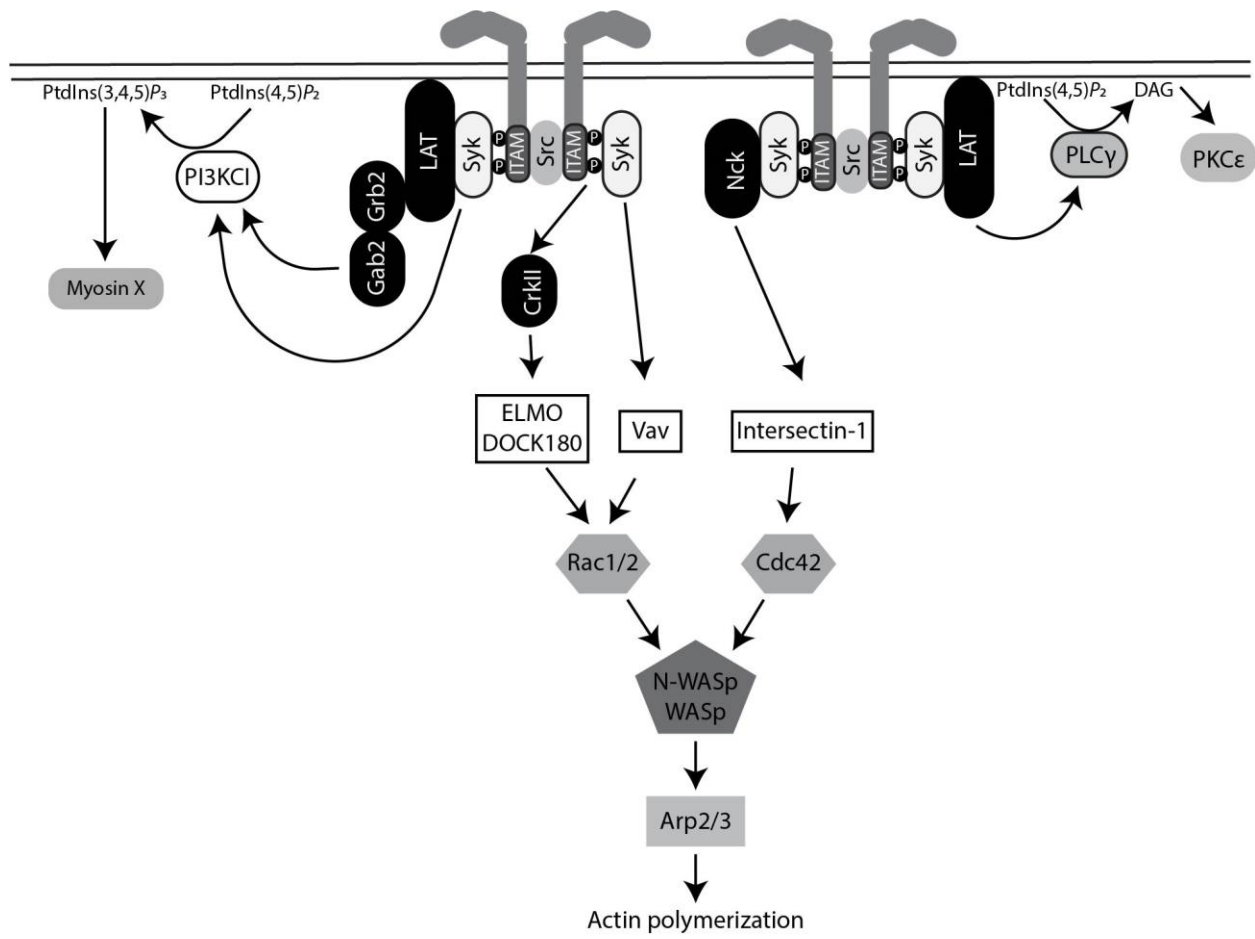

Figure 1.3.2: Fcγ receptor signaling. Activation of Fcγ receptor by multivalent IgG leads receptor clustering and activation of ITAM domains by Src-family kinases. Phosphorylation of the ITAM recruits Syk, followed by numerous adaptor proteins and other signaling mediators. The combined effect of various lipid and protein kinases, GTPases, and actin nucleators is the actin-dependent extension of pseudopods around the particle leading to particle internalization.

Chapter 2: Materials and methods

2.1 Cell culture and transfection

RAW 264.7 murine macrophages were purchased from ATCC (Manassas, VA). RAW macrophages with CRISPR knockouts of TFEB, TFE3, or TFEB and TFE3 were gifts provided by Dr. Rosa Puertollano at the National Institutes of Health (Pastore et al., 2016). HeLa cells were purchased from ATCC. All cell lines were cultured in the presence of Dulbecco's Modified Eagle's Medium (DMEM; Wisent, St. Bruno, QC or Gibco, Waltham, MA), supplemented with 5-10% fetal bovine serum (Wisent or Gibco), at 37°C and 5% CO_2.

Plasmids encoding TFEB-GFP, TFE3-GFP, and MiTF-GFP were gifts provided by Dr. Shawn Ferguson at Yale University (Roczniak-Ferguson et al., 2012). cDNA plasmids were introduced into RAW cells using FuGENE HD (Promega, Madison, WI) following manufacturer's guidelines at a 3.5:1 ratio of FuGENE HD to DNA. Briefly, 1.1 μg of DNA was diluted in water or serum-free DMEM to a concentration of 20 μg/mL and complexed with 3.9 μL of FuGENE HD. The transfection complex was mixed and incubated for 10 min before addition to RAW macrophages per 1 mL of complete media. Transfection reagents were washed off after 4 h and replaced with complete media. Experiments were performed 24 h post-transfection.

Gene silencing was performed against Rab7 with individual siRNA oligonucleotides (Dharmachon, Lafayette, CO) by electroporation using the Neon transfection system (Invitrogen, Waltham, MA). Briefly, ~6x10^6 RAW cells were grown to confluence in T-25 flasks. Cells were washed with in PBS, scraped and pelleted at 500 x g for 5 min. The cell pellet was resuspended in resuspension buffer R at a ratio of 100 μL per 1x10^6 cells and 200 nM of siRNA was added. The following oligonucleotides against mouse Rab7a (gene ID: 19349) were used: oligo 1 (open reading frame [ORF] J-040859-17-0002) or oligo 2 (ORF J-040859-18-0002). Cells were then

electroporated in 100 mL volumes with 1 pulse at 1730 V for 20 ms. After 24 hr, cells were

subjected to an additional round of knockdown and experiments were performed 48 h after initial

knockdown.

2.2 PIKfyve inhibition

Cells were treated with apilimod (20 nM unless otherwise stated, Toronto Research

Chemicals, Toronto, ON) at indicated times. Torin1 (100 nM, Tocris Bioscience, Minneapolis,

MN) was used as a positive control of TFEB nuclear localization for 1 h, unless otherwise stated.

2.3 Phagocytosis and endocytosis

IgG opsonized beads were prepared by incubating 3.0 mg/mL of IgG from human sera

(Sigma Aldridge, St. Louis, MO) with PBS in the presence of 15.0 mg/mL of beads. Depending

on the application, 3.0 μm polystyrene beads (Sigma Aldridge), 3.87 μm or 21.25 μm crosslinked

poly(styrene/divinylbenzene) beads (Bangs laboratories, Fishers, IN) were used. Beads were

opsonized by rotating end-over-end for 1 h at room temperature or overnight at 4°C. Opsonized

beads were briefly spun down and the supernatant was discarded. The bead pellet was washed

with 1 mL PBS and spun again. The final pellet was resuspended in 50 μL of PBS. For imaging

purposes, 5 μL of beads per 1 mL of complete DMEM was added to the cells, while 50 μL of

beads per 1 mL of complete DMEM was added for Western blotting.

Escherichia coli strain DH5-α was prepared by inoculating single colonies into liquid LB,

supplemented with ampicillin (100 μg/mL) where necessary. The culture was incubated

overnight at 37°C at 200 rpm overnight. Overnight cultures pelleted, washed with PBS, and

resuspended in PBS. *E. coli* was added to cells at a concentration of 0.06 OD per mL of complete DMEM for imaging or 0.6 OD per mL of complete DMEM for Western blot.

Inhibitors of Fcγ receptor signaling were added 10-30 min prior to addition of IgG-opsonized beads. Cells were inhibited with U-73122 (2 μM; U6756; Sigma Aldridge), dasatinib (1 μM, S1021, Selleck Chemicals; Houston, TX), LY-294-002 (100 μM, L9908; Sigma Aldridge) , U0126 (10 μM, Cell Signaling Technologies, Danvers, MA), cytochalisin D (10 μM, EMD Millipore, Burlington, MA), ZSTK474 (1 μM; S1072; Selleck). Inhibitors were present in the cell culture media throughout the experiment.

Phagocytic particles were parachuted onto RAW cells at 500 x *g* for 5 min and allowed internalize for 30 min at 37°C with 5% CO_2. Uninternalized particles were aspirated and fresh, complete media was added. The internalized particles were allowed to undergo maturation for the times indicated. The reactions were stopped by the addition of ice cold 4% PFA for imaging or 2x Laemmli sample buffer for Western blotting.

Heat-aggregated IgG were generated by heating 1.67 mg/mL IgG in PBS at 62°C for 20 min. Large aggregates were pelleted at 15,000 x *g* for 10 min and the supernatant was collected. Aggregated IgG was added to cells to a final concentration of 0.2 mg/mL of complete DMEM and endocytosed for 20-30 min at 37°C and 5% CO_2. External aggregated IgG was aspirated and fresh DMEM was added to allow for trafficking to the lysosome for 60 min.

Where necessary, torin1 (100 nM) was used as a positive control for TFEB nuclear localization for 1 h, unless otherwise stated.

Whole cell lysates were generated with 2x Laemmli sample buffer, or 1% Triton X-100

in PBS and mixed 1:1 with 2x Laemmli sample buffer. Lysates were supplemented with protease

inhibitor (Sigma-Aldrich) and/or PhosSTOP (Roche, Basel, Switzerland) where necessary.

Lysates were passed through 27-gauge needle until smooth and boiled. Puromycylation assays

were performed with the addition of 10 μg/mL of puromycin (EMD Millipore) 15 min before

cell lysis. Samples that required dephosphorylation were lysed in 1% Triton X-100. Lysates were

cleared by centrifugation at 16,000 x g for 10 min then subjected to Lambda protein phosphatase

(New England Biolabs, Ipswich, MA) as per manufacturer's instruction. Briefly, 20 μg of protein

was incubated with 50 mM HEPES, 100 mM NaCl, 2 mM DTT, 0.01% Brij 25, 1 mM $MnCl_2$,

and 8 units/μL of Lambda phosphatase at 30°C for 60 min. The reaction as stopped with 5x

Laemmli sample buffer and heated.

Most samples were resolved by SDS-PAGE though 8-12% acrylamide resolving gel. To

assay for TFEB mobility shift, we used an 8% acrylamide gel supplemented with 12.5 μM Phos-

tag acrylamide (Wako Chemicals U.S.A., Richmond, VA) and 25 μM $MnCl_2$. Phos-tag gels were

washed three times with 100 mM EDTA for 10 min each, and once with transfer buffer (25 mM

Tris-HCl, 192 mM glycine, 20% methanol). Proteins were transferred to PVDF and blocked with

5% skim milk or 3% BSA in Tris-buffered saline (1.5 mM NaCl, 500 μM Tris, pH 7.5) with

0.1% Tween-20 (TBST). Membranes were then incubated with primary and HRP-conjugated

secondary antibodies in the presence of the blocking buffer. Proteins were visualized using

Clarity Western enhanced chemiluminescence blotting substrates (Bio-Rad Laboratories,

Hercules, CA) with a ChemiDoc XRS+ or ChemiDoc Touch imaging system (Bio-Rad). Proteins

were quantified using Image Lab software (Bio-Rad) by normalizing against loading control and then normalizing against vehicle-treated control samples.

Rabbit monoclonal antibodies used were against cathepsin D (1:1000, GTX62603, GeneTex Inc., Irvine, CA), HSP60 (1:1000, 12165, Cell Signaling Technologies), p70-S6 kinase (1:1000, 2708, Cell Signaling), Rab7 (1:1000, 9367, Cell Signaling), p44/42 MAPK (1:1000, 4695, Cell Signaling), phospho-Thr202/Tyr204 p44/42 MAPK (1:1000, 4377, Cell Signaling), and GSK3α/β (1:1000, 5676, Cell Signaling). Rabbit polyclonal antibodies were used against ATP6V1H (1:1000, GTX110778, GeneTex), TFEB (1:2000, A303-673A, Bethyl Laboratories, Montgomery, TX), phospho-Thr389-p70-S6 kinase (1:1000, 9205, Cell Signaling), β-actin (1:1000, 4967, Cell Signaling), phospho-Ser9 GSK3β (1:1000, 9336, Cell Signaling), phospho-Ser21/9 GSK3α/β (1:1000, 9331, Cell Signaling), and phospho-S142 TFEB (1:500, ABE1971-I, EMD Millipore). Rat monoclonal antibodies were used against LAMP1 (1:200, 1D4B, Developmental Studies Hybridoma Bank, Iowa City, IO). Mouse monoclonal antibodies were used against puromycin (1:1000, 540411, EMD Millipore), and p53 (1:1000, 2524, Cell Signaling). Secondary HRP-conjugated antibodies were raised in donkey (1:10000, Bethyl).

2.5 Immunofluorescence

Cells were fixed with 4% ice cold paraformaldehyde in PBS for 20 min at room temperature, followed by incubation with 50 mM L-glycine in PBS for 20 min. Cells were then permeabilized and concurrently blocked using 0.2% Triton X-100 and 2% BSA in PBS for 60 min. Alternatively, cells were fixed and permeabilized with ice cold methanol for 5 min at -20°C, followed by blocking with 2% BSA in PBS for 60 min. Primary antibodies at the indicated concentrations were applied for 60 min, followed by secondary antibodies. were applied in PBS

at the concentrations indicated for 60 min, followed by 3 PBS washes for 5 min each. Secondary

antibodies were applied for 60 min at their respective concentrations in PBS, followed by 5 PBS

washes for 5 min each. Where necessary, DAPI (Roche) was applied to stain the nucleus at 5

ng/mL in PBS. Cells were then mounted onto glass slides with Dako fluorescent mounting media

(Dako, Santa Clara, CA). Rabbit monoclonal antibodies were used against TFEB (1:250, A303-

673A, Bethyl). Donkey polyclonal antibodies conjugated to Dylight (1:500, Bethyl) or cyanine

(1:1000, Jackson Immunoresearch, West Grove, PA) fluorescent dyes were used as secondary

antibodies.

2.6 Lysosome labelling for live-cell imaging

Lysosomes for manual counting were treated with inhibitors before microscopy. Cells

with fluorescently labelled lysosomes were incubated with 2.5 mg/mL of Lucifer yellow

(Invitrogen) in complete media for 2 h at 37°C and 5% CO_2. Cells were washed with PBS 3

times, and fresh complete media was added to the cells. The fluid phase marker was allowed to

traffic to the lysosome for 1 h prior to application of inhibitors. Following treatment, cells were

taken to the microscope and imaged.

2.7 Epifluorescence and spinning disk confocal microscopy

Cells transfected with GFP-fused MiT/TFE family members and manual counting of

lysosomes were imaged with a Leica DM5000B system and a DFC350FX camera controlled by

Leica application suite (Leica Microsystems Inc., Concord, ON). Endogenous TFEB with

PIKfyve inhibition in RAW cells were imaged with an Olympus IX83 microscope with a

Hamamatsu ORCA-Flash4.0 digital camera controlled by CellSens Dimensions software

(Olympus Canada Inc., Richmond Hill, ON). These images were processed by deconvolution using a constrained iterative in CellSens Dimensions. All other imaging of live and fixed cells used a Quorum DisKovery spinning disc confocal microscope system with a Leica DMi8 microscope equipped with an Andor Zyla 4.2 Megapixel sCMOS camera or Andor iXON 897 EMCCD camera, controlled by Quorum Wave FC powered by MetaMorph software (Quorum Technologies, Guelf, ON). Live-cell imaging was done using cell-specific serum-free media without phenol red in a 5% CO_2 champers at 37°C.

2.8 Image analysis

Cells transfected with GFP-fused TFEB, TFE3, or MiTF were imaged and quantified by comparing the mean cytosolic and nuclear fluorescence intensity using ImageJ. Cells with greater signal in the cytosol over the nucleus were considered cytosolic while cells with greater nuclear signal compared to the cytosol were counted as nuclear. Quantifications were expressed as the percentage of cells having greater mean fluorescence intensity in the nucleus compared to the cytosol. Cells stained for endogenous TFEB were quantified by taking the ratio of the mean nuclear fluorescence, as indicated by DAPI counter-stain, over the mean cytosolic fluorescence on ImageJ.

To manually quantify vacuole diameter, vacuoles were measured on ImageJ and defined with a minimum diameter of 1.5 μm. The number of vacuoles and diameter were scored against the total number to get the mean vacuole number and diameter. To determine the volume and number of fluorescently-labelled lysosomes, Z-stacks were imported into Icy bioimage software, equipped with 3D analysis and split ROI plugin. Regions of interest were drawn around whole cells and using the spot detector tool, bright spots were detected over a dark background with a

54

scale of 3 (~7 pixels) with 140-sensitivity. Spots were automatically split using the split ROI plugin, and volume information was extracted using the 3D analysis plugin. Alternatively, Z-stacks were imported into Volocity (Volocity 6.3.0, Perkin Elmer, Waltham, MA). Images were thresholded with a value 2x the mean background signal, excluding particles less than 0.3 μm^3. The number and volume of lysosomes were averaged over the total number of cells analyzed.

2.9 Quantitative Real Time Polymerase Chain Reaction

Total RNA was extracted from RAW cells with GeneJET RNA purification kit (Thermo Fisher Scientific, Waltham, MA) as per manufacturer's instruction. Equal quantities of RNA were reverse transcribed with SuperScript VILO cDNA synthesis kit (Invitrogen) following manufacturer's guidelines. The resulting cDNA was diluted 1:100 and amplified for quantitative PCR on a Step One Plus Real-Time PCR thermal cycler (Applied Biosystems, Waltham, MA) with Step One Software (V2.2.2, Applied Biosystems) in the presence of TaqMan Fast Advanced Master Mix (Invitrogen). The TaqMan gene expression assays (Invitrogen) for the reference gene ABT1 (Mm00803824_m1) and target genes CTSD (Mm00515586_m1), ATP6V1H (Mm00505548_m1), ATP6V1D (Mm00445832_m1), LAMP1 (Mm00495262_m1), and MCOLN1 (Mm00522550_m1) were assayed in technical triplicates. Target gene expression was determined by relative quantification (ΔΔCt method) to ABT1 and the vehicle-treated control sample.

2.10 Phosphoinositide labeling and measurement by HPLC-coupled flow scintillation

RAW cells were cultured for 24 h in inositol-free DMEM (MP biomedical, Santa Ana, CA) with 10 µCi/mL *myo*-[2-^{3}H(N)] inositol (Perkin Elmer), 10% dialyzed FBS (Gibco), 4 mM

L-glutamine (Sigma Aldrich), and 1x insulin-transferrin-selenium-ethanolamine (Gibco). Cells were then drug treated with 20 nM apilimod or 100 nM torin1 for 1 hr. Reactions were stopped with 600 μL of 4.5% perchloric acid (v/v) on ice for 15 min. The precipitated phospholipids were scraped and pelleted at 12,000 x g for 10 min at 4°C. Pellets were washed with 1 mL of ice cold 0.1 M EDTA, pH 8.8 and pelleted again. The phospholipid pellet was resuspended in 50 μL of water and deacylated in the presence of 500 μL of 45.7% methanol: 10.7% methylamine: 11.4% 1-butanol (v/v) for 20 min at room temperature followed by incubation at 53°C for 50 min. Sample were vacuum-dried and washed twice by resuspending in 300 μL of water and drying. The final dried pellet was resuspended in 450 μL of water. The gro-inositol was extracted in the presence of 300 μL of 80% 1-butanol, 16% ethyl ether, and 4% ethyl formate. The samples were vortexed for 5 min, and the layers were separated by centrifugation at 12,000 x g for 2 min. The bottom, aqueous layer was collected and extracted twice more. The final aqueous layer was vacuum-dried and resuspended in 50 μL of water. Equal counts of ^{3}H were separated by HPLC (Agilent Technologies, Santa Clara, CA) through a strong anion exchange 4.6 x 250-mm column (Phenomenex, Torrance, CA or Hihrom, Berkshire, England) with a flow rate of 1 mL/min and subjected to a gradient of water (buffer A) and 1 M $(NH_4)_2HPO_4$, pH 3.8 (adjusted with phosphoric acid) (buffer B) as follows: 0% B for 5 min, 0 to 2% B for 15 min, 2% B for 80 min, 2 to 10% B for 20 min, 10% B for 30 min, 10 to 80% B for 10 min, 80% B for 5 min, 80 to 0% B for 5 min. The radiolabeled eluate was detected by β-RAM 4 (LabLogic, Brandon, FL) with a 1:2 ratio of eluate to scintillant (LabLogic) and analyzed by Laura 4 software. PtdInsPs were identified by time of elution and each PtdInsP peak was normalized against the parent phosphatidylinositol peak. Relative abundance of PtdInsPs from each treatment condition was then compared against their respective abundance in the vehicle-treated control condition.

2.11 Flow Cytometry and DQ-BSA Proteolysis

Cells were pre-treated with heat-aggregated IgG continuously for the times indicated prior to lysosome labelling. Lysosomes were co-labeled with 2 μM fixable Alexa Fluor 647-conjugated 10 kDa dextran (Invitrogen) and 10 μg/ml DQ Green BSA (Invitrogen) for 15 min, followed by a wash with PBS and allowed to traffic to the lysosome for 1 h in cell culture media. Cells were chilled with ice cold PBS, scraped, and analyzed for whole-cell fluorescence using the BD FACSCalibur flow cytometer (BD Biosciences, Franklin Lakes, NJ), where 10,000 events were counted per sample per condition using the channels for their respective fluorescence profiles. Background signal was determined with non-labeled cells. The DQ-BSA signal was then normalized against dextran specific signal.

2.12 Statistical analysis

All experiments were done at a minimum of three independent biological replicates, unless otherwise stated. Microscopy images were analyzed for at least 30 cells in each replicate. In most cases, Student's t-tests were used to compare a sample against their control condition with statistical significance of $\alpha=0.05$. One-way ANOVA was used for three or more conditions with $\alpha=0.05$. When samples were normalized, multiple t-tests with Bonferroni correction were applied to increase confidence.

Chapter 3: Results

<u>3.1 TFEB activation through PIKfyve inhibition does not contribute to lysosome enlargement.</u>

<u>3.1.1 PIKfyve inhibition induces TFEB nuclear translocation.</u>

PIKfyve is responsible for generating PtdIns(3,5)P_2, a lysosomal lipid necessary for maintaining many lysosome functions including lysosome size (Ikonomov et al., 2015; Rutherford, 2006; Yamamoto et al., 1995). Loss of PtdIns(3,5)P_2 leads to enlarged lysosomes, a process currently thought to occur due to endomembrane trafficking defects (Bissig et al., 2017; Dove et al., 2002; Rutherford, 2006). However, increased lysosome biogenesis via TFEB activation had not been considered. We hypothesized that inhibition of PIKfyve would induce TFEB activation and enhanced *de novo* lysosome biosynthesis that contributes to lysosome enlargement. Specifically, loss of PIKfyve activity may inhibit mTORC1 function, leading to
TFEB nuclear localization. To investigate the possible role of TFEB-mediated lysosome biogenesis on during PIKfyve inhibition, we employed the murine RAW 264.7 macrophage cell line. These cells are professional phagocytes and rely on their lysosomes for pathogen clearance (Schlam et al., 2015; Sigola, Fuentes, Millis, Vapenik, & Murira, 2016). Previous work in our lab showed that inhibition of PIKfyve in RAW cells induces the vacuolation phenotype that can be seen under light microscopy, providing an observable and easily quantifiable phenotype (Ho et al., 2015; G. H. E. Kim et al., 2014).

To deplete PtdIns(3,5)P_2 in RAW cells, we pharmacologically inhibit the PIKfyve kinase by using apilimod (Figure 3.1.1A). Apilimod was explored as a possible therapeutic for autoimmune diseases, including Crohn's disease and rheumatoid arthritis, where expression of

the proinflammatory cytokines interleukin-12 (IL-12) and IL-23 are elevated. Use of apilimod reduced IL-12/23 levels in part by binding to the kinase domain of PIKfyve, blocking lipid kinase activity and reducing PtdIns(3,5)P_2 levels (Cai et al., 2013). In our system, PtdIns(3,5)P_2 was reduced by >75% with 20 nM apilimod for 1 h (Figure 3.1.1B) (Ho et al., 2015). Concurrently, depletion of PtdIns(3,5)P_2 lead to enlarged lysosomes that were visible through DIC optics (Figure 3.1.1C) or fluorescently labelled lysosomes (Figure 3.1.1D).

Using these conditions, we tracked TFEB localization in RAW cells by expressing TFEB-GFP or staining for endogenous TFEB. Cells expressing TFEB-GFP increased nuclear localization from $22.5 \pm 7.5\%$ in control cells to $100 \pm 0\%$ of cells after 1 h of apilimod exposure (Figure 3.1.2A). For comparison, we induced TFEB nuclear localization by blocking mTORC1 with torin1, an ATP-competitive inhibitor for mTOR (Thoreen et al., 2009). TFEB-GFP nuclear localization with torin1 was comparable to apilimod treatment, with $97.0 \pm 3.0\%$ having nuclear TFEB-GFP (Figure 3.1.2A). Similarly, apilimod treatment increased the nuclear-to-cytosolic ratio of endogenous TFEB to 0.92 ± 0.03 compared to 0.55 ± 0.04 in vehicle-treated cells (Figure 3.1.2B). Additionally, we checked whether PIKfyve inhibition would induce TFEB nuclear localization in other cell types. In HeLa cells, TFEB nuclear-to-cytosolic ratio also increased from 0.57 ± 0.09 in control cells to 1.15 ± 0.07 in apilimod-treated cells (Figure 3.1.2C), suggesting apilimod-induced TFEB nuclear localization is not exclusive to macrophages.

Finally, since MiTF and TFE3 appear to cooperate with TFEB in many scenarios (Martina et al., 2014; Ploper et al., 2015), we evaluated their localization in RAW cells. Both TFE3-GFP (Figure 3.1.3A) and MiTF-GFP (Figure 3.1.3B) localized to the nucleus in >90% of cells after apilimod treatment compared to >40% in vehicle-treated cells. Together, these results

show that PIKfyve inhibition with apilimod induces nuclear localization of MiT/TFE family members and suggest further cooperativity by these family members.

3.1.2 PIKfyve inhibition increases dephosphorylation of TFEB

TFEB nuclear localization is primarily driven by dephosphorylation of key serine residues throughout the protein (Puertollano et al., 2018). Traditionally, others have relied on gel mobility shifts to detect changes in TFEB phosphorylation in whole cell lysates (Puertollano et al., 2018; Roczniak-Ferguson et al., 2012; Settembre et al., 2011), where increased gel mobility is assumed to result from TFEB dephosphorylation. To confirm that TFEB phosphorylation status changed in PIKfyve inhibited cells, we supplemented our SDS-PAGE gels with Phos-tag acrylamide. When complexed with a divalent cation, either Mn^{2+} or Zn^{2+}, Phos-tag separates proteins by phosphorylation abundance or position with much higher resolution than typical SDS-PAGE, in addition to molecular weight (Kinoshita, Kinoshita-Kikuta, Takiyama, & Koike, 2006). Therefore, a single band can be resolved into multiple bands based on phosphorylation, with the least phosphorylated species running the fastest.

Running whole cell lysates through these Phos-tag gels resulted in a distinctive banding pattern (Figure 3.1.4, lane 2). To confirm that the antibody is specific for TFEB, we also ran a whole cell lysate from RAW cells knocked out for *tfeb*[-/-] by CRISPR/Cas9 (Figure 3.1.4, lane 1). Qualitatively, apilimod-treated RAW cells had a distinct TFEB banding pattern relative to the vehicle-treated control (Figure 3.1.4, lane 4 & 2 respectively). Interestingly, the pattern observed with apilimod treatment was similar to the torin1 treatment (Figure 3.1.4, lane 4 & 3 respectively). For comparison, we subjected the whole cell lysates to lambda protein phosphatase to dephosphorylate TFEB further (Figure 3.1.4, lane 5, 6 & 7). In all cases, application of lambda

phosphatase collapsed all bands into a single, faster running band, suggesting that TFEB retains

some phosphorylation with apilimod or torin1.

3.1.3 TFEB dephosphorylation may result from inhibition of GSK3 but not mTORC1 or ERK2.

mTORC1 is reported to be recruited and activated by PtdIns(3,5)P_2 in yeast and

adipocytes (Bridges et al., 2012; N. Jin et al., 2014). Thus, activation of TFEB in PIKfyve-

inhibited cells may result from inhibition of mTORC1 during PtdIns(3,5)P_2 depletion. To test

this, we evaluated the phosphorylation status of p70-S6K (S6K hereafter) as a reporter for

mTORC1 activity. When active, mTORC1 phosphorylates S6K at Thr389 (Pearson et al., 1995).

Under resting conditions, cells were fully fed with amino acids and growth factors and S6K is

phosphorylated (Figure 3.1.5A, lane 1). When mTORC1 was inhibited with torin1, S6K

phosphorylation significantly decreased to $5.6 \pm 4.4\%$ of control (Figure 3.1.5A, lane 2). In

comparison, S6K phosphorylation was not significantly reduced in apilimod-treated cells

compared to the vehicle-treated control cells, suggesting that mTORC1 remains active during

PIKfyve inhibition (Figure 3.1.5A, lane 3, 4 & 5). This is consistent with previous reports that

PIKfyve inhibition does not block mTORC1 activity (Krishna et al., 2016; W. Wang et al.,

2015).

To test the possibility that mTORC1 may act upstream of PIKfyve, we checked the

abundance of PtdIns(3,5)P_2 during mTORC1 inhibition (Figure 3.1.5B). While apilimod-treated
cells displayed a $78 \pm 10\%$ reduction in PtdIns(3,5)P_2, mTORC1 inhibition with torin1 did not

reduce PtdIns(3,5)P_2 levels (Figure 3.1.5B). Instead, the levels of PtdIns(3,5)P_2 increased to 132

± 14% of control. Taken together, TFEB nuclear localization during apilimod treatment does not appear to be a result of mTORC1 inactivation.

Next, we investigated the role of other known kinases that can modulate TFEB phosphorylation. ERK2 was the first kinase suggested to phosphorylate TFEB at S142 and to control cytosolic-nuclear localization (Settembre et al., 2011). To assay ERK2 activity, we probed for phosphorylation of ERK2 (Figure 3.1.6). Activation of ERK2 correlates with phosphorylation levels of ERK2 at T185 and Y187 (Payne et al., 1991). Phosphorylation of ERK2 in control cells is ablated by the ERK specific inhibitor U0126, reducing phosphorylation to 20 ± 10% of control (Figure 3.1.6A, lane 2, B). Inhibition of ERK with U0126 also reduced phosphorylation of ERK1 (Figure 3.1.6C). However, there was no significant difference in ERK2 phosphorylation in apilimod-treated cells compared to control cells (Figure 3.1.6A, lane 3, 4 & 5, B). This suggests that ERK2 remains active during apilimod treatment and is not responsible for TFEB nuclear localization.

We also evaluated the contributions of GSK3β. GSK3β was suggested to phosphorylate TFEB independently of mTORC1 at Ser134 and Ser138 (L. Li et al., 2018; Y. Li et al., 2016). GSK3 comes in two isoforms, GSK3α and GSK3β. Activity of GSK is inversely correlated to phosphorylation at Ser21 and Ser9, respectively (Sutherland & Cohen, 1994; Sutherland, Leighton, & Cohen, 1993). Phosphorylation at these residues creates a pseudo-substrate that competitively binds to the active site of GSK3, blocking entry of other substrates, resulting in autoinhibition (Frame, Cohen, & Biondi, 2001). Therefore, increased phosphorylation of GSK3α/β is related to decreased activity. Compared to control cells, apilimod-treatment appeared to increase phosphorylation of both GSK3 isoforms (Figure 3.1.7). After 1 h, GSK3α phosphorylation increased 1.7 ± 0.4 times relative to control (Figure 3.1.7A, lane 5), while

GSK3β phosphorylation increased 2.2 ± 0.4 fold relative to control (Figure 3.1.7B, lane 5). For comparison, we used torin1 as a positive control for GSK3 inhibition, as S6K can phosphorylate GSK3 (Cross, Alessi, Cohen, Andjelkovich, & Hemmings, 1995). Torin1-treated cells reduced GSK3α and GSK3β phosphorylation to 0.61 ± 0.02 fold (Figure 3.1.7A, lane 2) and 0.58 ± 0.09 fold of control (Figure 3.1.7B, lane 2). To further investigate the role of GSK3 on TFEB nuclear localization, we transfected our cells with constitutively active GSK3β where S9 is mutated to alanine. Loss of this phospho-site keeps the active site of GSK3β free and uninhibited. However, co-expression of GSK3β-S9A with TFEB-GFP did not reduce TFEB nuclear localization significantly compared to wild-type GSK3β during PIKfyve inhibition (Figure A1.1). However, this result is not conclusive. GSK3 signaling is complex with many factors influencing activity, including localization, phosphorylation, redundancy between isoforms, and expression levels of the mutant relative to endogenous (Bechard & Dalton, 2009; Cole, Frame, & Cohen, 2004; Patel & Woodgett, 2017). Thus, further work needs to be done to validate the contribution of GSK3 in this pathway. While GSK3 may not alter TFEB activation in PIKfyve-inhibited cells, the relationship between GSK3 and PIKfyve may be worth exploring as a previously unreported connection.

3.1.4 Acute PIKfyve inhibition does not increase lysosomal protein expression

PIKfyve inhibition leads to lysosome enlargement, that may require *de novo* lysosome biogenesis. TFEB is known as a master regulator of lysosome biogenesis by increasing expression of CLEAR network genes (Sardiello et al., 2009). To evaluate changes in gene expression in our system, we specifically monitored the levels of the aspartyl protease cathepsin D, the membrane protein LAMP1, the calcium channel MCOLN1, and two subunits of the V-

ATPase, ATP6V1H and ATP6V1D. After 3 h of PIKfyve inhibition, the mRNA levels of all five

genes were significantly increased by 33-98% over control (Figure 3.1.8A, apilimod-treated).

These changes to transcription compared favourably to the changes in gene expression during

mTOR inhibition in the same time frame (Figure 3.1.8A, torin1-treated). To further confirm *de*

novo lysosome biosynthesis in PIKfyve-inhibited cells, we checked the protein abundance of the

corresponding genes. Surprisingly, protein levels of cathepsin D and V-ATPase V1H did not

increase with 3 or 6 h of PIKfyve inhibition (Figure 3.8B, C). LAMP1 showed a slight, but

significant increase of $27 \pm 6\%$ after 6 h of PIKfyve inhibition, many hours after TFEB nuclear

localization and lysosome enlargement. This increase in LAMP1 may be consistent with

increases in LAMP2, another lysosome membrane protein, observed by Ferguson et al., possibly

due to autophagosome build up during PIKfyve inhibition (Cole J. Ferguson et al., 2009). These

results may suggest lysosome biogenesis does not contribute to acute lysosome enlargement.

3.1.5 Biosynthesis is not required for acute lysosome enlargement in PIKfyve inhibited cells.

Since lysosomal protein abundance does not appear to increase until many hours after

TFEB nuclear localization, we aimed to understand whether TFEB was dispensable for acute

lysosomal enlargement. If TFEB contributed to lysosome enlargement, lysosomes during

PIKfyve inhibition of TFEB knockout cells may be smaller compared to wild-type cells. To do

this, we obtained RAW cells knocked out for *tfeb*[-/-], *tfe3*[-/-], or both from the Puertollano lab

(Pastore et al., 2016) to evaluate the number and size of lysosomes during PIKfyve inhibition.

First, we manually analyzed vacuole diameter using DIC optics by arbitrarily defining vacuoles

has having a diameter greater than 1.5 μm. Using this metric, we counted the number and

measured the diameter of vacuoles present in *tfeb*[-/-] and/or *tfe3*[-/-] cells after 1 h. Consistent with

the lack of protein increase, *tfeb*[-/-] and/or *tfe3*[-/-] RAW cells did not have significantly fewer (Figure 3.1.9A, bottom left) or smaller (Figure 3.1.9B, bottom right) vacuoles compared to wild-type RAW cells (3.6 ± 0.5 vacuoles with average diameter of 2.9 ± 0.5 μm) when treated with apilimod.

We followed up these results by performing more robust, volumetric analysis of prelabeled lysosomes to determine the number and volume of each lysosome. In collaboration with Dr. Matthew Gray, we found that *tfeb*[-/-] and/or *tfe3*[-/-] cells did not have significantly fewer lysosomes or significantly less lysosomes volume compared to wild-type RAW cells during apilimod-treatment (Figure 3.1.9B). These results suggest that TFEB and/or TFE3 are not required for acute lysosomal enlargement in apilimod-treated cells. Since MiTF can also contribute to lysosome biogenesis, we ruled out redundancy by analyzing the lysosome volume in HeLa cells knocked out for *tfeb*[-/-], *tfe3*[-/-] and *mitf*[-/-] by CRISPR/Cas9, gifted to us by the Youle lab (Nezich et al., 2015). In collaboration with Golam Saffi, he showed that triple knockout cells were not significantly different with respect to lysosome number, volume per lysosome, or total volume per cell compared to wild-type HeLa cells (Figure A1.2) (Choy et al., 2018). Consistent with RAW cells, the number and size of lysosomes during PIKfyve-inhibition do not change in the presence or absence of MiT/TFE family members in HeLa cells.

To further confirm that protein synthesis is not required for acute lysosome enlargement during PIKfyve inhibition, we blocked translation using cycloheximide. Cycloheximide is an antibiotic produced by *Streptomyces griseus* that blocks protein elongation by binding to the E-site of the 60S ribosome (Schneider-Poetsch et al., 2010). Consistent with our previous results, cells treated with cycloheximide did not reduce the average number or volume of lysosomes (Figure 3.1.10A). Cells treated with apilimod and cycloheximide had 29 ± 13 lysosomes with an

average volume of 8.1 ± 2.1 μm^3, while cells treated with apilimod alone had 30 ± 9 lysosomes

having 8.3 ± 2.5 μm^3 average volume. Efficacy of cycloheximide was evaluated by puromycin

incorporation assay and by checking the abundance of fast turnover protein p53. Puromycin

blocks protein translation by prematurely terminating peptide elongation after its incorporation

into growing peptides (Yarmolinsky & Haba, 1959). In control cells, puromycin labelled proteins

that were actively translated, while cycloheximide largely blocked the production of

puromycylated proteins (Figure 3.1.10B, lane 3 & 4). Similarly, p53 is a fast turnover protein

with a half-life less than 20 minutes (Giaccia & Kastan, 1998). Blocking translation with

cycloheximide blocks synthesis of new p53 while allowing turnover of existing p53. In

accordance, p53 abundance was significantly reduced to $19.6 \pm 5.1\%$ in cycloheximide-treated

cells compared to the vehicle-treated control. Together, these results suggest that protein

synthesis is not required for lysosome enlargement during PIKfyve inhibition.

Although *de novo* biosynthesis may not be required for acute lysosome enlargement, we

noticed that in all cases, the number of individual lysosomes decreased while the volume of

individual lysosomes increased during PIKfyve inhibition. We hypothesized that there may be an

imbalance in the relative fusion-fission rates of lysosomes, shifting towards increased rates of

lysosome fusion during PIKfyve inhibited. Therefore, blocking lysosome fusion during PIKfyve

inhibition may prevent lysosome enlargement and reduction in lysosome number. By blocking

components of lysosome fusion during PIKfyve inhibition, lysosomes became smaller and cells

resisted lysosome enlargement and retained higher lysosome number compared to apilimod-only

treated cells. This work was also featured in our journal publication by my co-first author, Golam

Saffi (Choy et al., 2018). Overall, despite TFEB activation during PIKfyve inhibition, TFEB is

not required for lysosome enlargement. Furthermore, *de novo* lysosome biosynthesis appears to

be dispensable for acute lysosome enlargement during PIKfyve inhibition. Further work should

be done to understand the functional consequence of TFEB activation during PIKfyve inhibition.

3.2 Phagocytosis induces TFEB nuclear localization and enhances proteolysis

3.2.1 Fcγ receptor engagement leads to TFEB nuclear localization

Overexpression of TFEB enhances degradation of lysosomal cargo (Settembre et al., 2011). Similarly, phagocytosis of microbes by phagocytes sequesters the potential pathogens in a membrane-bound phagosome. These phagosomes are subsequently degraded by the lysosome to neutralize the potential pathogens (Wong et al., 2017). We wondered if phagocytic cells activated TFEB-dependent lysosome biogenesis to enhance degradation of their phagosomes. To
test whether TFEB was activated by phagocytosis, we challenged RAW macrophages with IgG-opsonized beads. After 30 min of internalization, $67 \pm 6\%$ of cells had nuclear TFEB-GFP after a 60 min chase period compared to $7 \pm 2\%$ resting cells (Figure 3.2.1A). Likewise, the nuclear-to-cytosolic ratio of endogenous TFEB increased to 1.3 ± 0.6 after 60 min of phagocytosis from 0.3 ± 0.1 in control cells (Figure 3.2.1B). We wondered if Fcγ receptor engagement was sufficient to induce nuclear localization of TFEB. Therefore, we challenged our cells with heat-aggregated IgG, multivalent forms of IgG that are internalized by endocytosis (Tse et al., 2003). Endocytosis via the Fcγ receptor led to increased nuclear localization of cells expressing TFEB-GFP in as little as 10 minutes ($56 \pm 26\%$) compared to resting cells ($18 \pm 9\%$), with TFEB-GFP nuclear localization plateauing after 60 min ($97 \pm 2\%$) (Figure 3.2.1C).

We also investigate whether TFEB nuclear localization could be generalized to the immune response. To evaluate the role of other immune stimuli, we challenged our cells with cytokines. These are chemical messages secreted by immune cells that can polarize macrophages (Martinez & Gordon, 2014). We use interferon γ (IFNγ) and IL-12 as pro-inflammatory

cytokines, and IL-4 and IL-10 as anti-inflammatory cytokines. In all cases, TFEB-GFP did not increase in its nuclear localization even after 4 h of stimulation compared to the control condition ($24 \pm 4\%$) (Figure 3.2.2). Taken together, TFEB nuclear localization may specifically respond to specific immunological stimuli, rather than all immune signals.

3.2.2 Lysosomes become more proteolytic after TFEB-induced lysosome biogenesis

Lysosome gene transcription coincides with TFEB nuclear localization (Sardiello et al., 2009). To check if lysosome gene expression increased with IgG-opsonized beads, we checked the mRNA levels of the protease CTSD, subunit of the V-ATPase ATP6V1H, membrane protein LAMP1, and calcium channel MCOLN1. In collaboration with Dr. Matthew Gray, we showed that only some genes were upregulated with phagocytosis (Figure 3.2.3A). Specifically, ATP6V1H and CTSD increased >50% relative to control after 4 h of phagocytosis. In contrast, there was no significant increase in LAMP1 or MCOLN1 (Figure 3.2.3A). For comparison, RAW cells treated with torin1 for the same time frame significantly increased mRNA of all genes as seen previously (Figure 3.2.3A, Figure 3.1.8A). Furthermore, work done by Dr. Gray showed TFEB activation by heat-aggregated IgG did not increase lysosome number (Figure A1.3) (Gray et al., 2016). Together, the selective increase in ATP6V1H and CTSD may make existing lysosome more acidic and more proteolytic, rather than make more lysosomes.

TFEB-mediated lysosome biogenesis was previously shown to enhance degradation of cargo (Sardiello et al., 2009). To test the hypothesis that lysosomes become more proteolytic, we track the fluorescence of dye-quenched bovine serum albumin (DQ-BSA). This BSA molecule is heavily labeled with a BODIPY fluorescent dye such that the emission fluorescence is quenched. As the molecule is degraded by the lysosomes, the BODIPY is liberated and increases

70

fluorescence. In this way, increased fluorescence from DQ-BSA suggests increased proteolysis

by the lysosome. We pre-activate TFEB by challenging RAW macrophages with aggregated IgG

for 2 for 6 h and allow TFEB activation to upregulate lysosome biogenesis. After the incubation

period, DQ-BSA was endocytosed and the fluorescence emitted was observed by flow

cytometry. To control for rates of endocytosis, cells co-endocytosed a fluorescent dextran. In

collaboration with Monica Dayam, we showed that pre-activation of TFEB enhanced

fluorescence of DQ-BSA relative to the control cells in a time dependent manner. Compared to

control, 2 h pre-treatment with aggregated IgG increased DQ-BSA fluorescence by $34 \pm 16\%$

while 6 h pre-treatment enhanced DQ-BSA fluorescence by $68 \pm 32\%$ (Figure 3.2.3B). Together,

these results suggest that Fcγ receptor activation leads to more degradative lysosomes.

3.2.3 Phagocytosis leads to TFEB dephosphorylation

TFEB becomes active in response to autophagy to make more lysosomes for

autophagosomes degradation (Settembre et al., 2011). Specifically, TFEB activation is dependent

on loss of phosphorylation by mTORC1 inactivation and calcineurin activation (Medina et al.,

2015; Roczniak-Ferguson et al., 2012). To understand how the Fcγ receptor activates TFEB to

enhance degradation of phagosomes, we first checked the phosphorylation status of TFEB using

a combination of standard SDS-PAGE gels and Phos-tag gels, with total TFEB antibody or

phospho-S142 TFEB antibody (Figure 3.2.4). In addition to IgG beads, we also used *E. coli* as a

more physiological model. In standard SDS-PAGE gels (Figure 3.2.4A,C), total TFEB mobility

increased when RAW cells were challenged with phagocytic targets (Figure 3.2.4A). This

change in mobility is comparable to mTOR inhibition with torin1 (Figure 3.2.4A, lane 4). Using

Phos-tag gels, we also saw a redistribution of various slower-moving TFEB bands in the control

condition to faster running bands in cells that phagocytosed particles (Figure 3.2.4C). We

compared these Western blots against total TFEB to blots probed with anti-pS142 antibodies

(Figure 3.2.4B,D). TFEB is thought to be phosphorylated by mTORC1 and/or ERK2 at S142,

modulating nuclear localization (Puertollano et al., 2018). With SDS-PAGE gels, the pTFEB

antibody strongly detects a slow running band in control cells (Figure 3.2.4B, indicated with **).

Phagocytosis lead to the enrichment of a faster running band (Figure 3.2.4B, indicated with *).

This same pattern appears in Phos-tag gels stained for pTFEB (Figure 3.2.4D). Together, these

results suggest phagocytosis induces TFEB dephosphorylation, producing banding patterns

distinct from control cells. Despite the many possible phosphorylation sites, TFEB appears to

retain the phosphorylation of S142 during phagocytosis. Further investigation will be required to

understand the specific bands detected by the pS142 antibody and how these forms of TFEB are

phosphorylated.

To examine the role of mTORC1 inactivation on TFEB dephosphorylation, we checked

the phosphorylation status of S6K. Again, S6K phosphorylation at T389 is proportional to

mTORC1 activity. RAW cells challenged with IgG-opsonized beads or *E. coli* did not decrease

S6K phosphorylation (Figure 3.2.5). Together, these results suggest TFEB activation is

dependent on dephosphorylation despite consistent activation of mTORC1 during phagocytosis.

3.2.4 Fcγ receptor signaling leading to actin polymerization is required for TFEB nuclear
localization

The signaling pathway downstream of the Fcγ receptor is complex, activating many

signaling branches that culminate in the polymerization of actin and membrane remodelling to

enact particle internalization (Flannagan, Jaumouillé, & Grinstein, 2012). Since mTORC1

remains active during phagocytosis, we hypothesized that some aspect of Fcγ receptor may

regulate TFEB activation. To understand the signaling requirements for TFEB nuclear

localization, we targeted key junctions in Fcγ receptor signaling (Figure 3.2.6A). Engagement of

Fcγ receptors leads to receptor clustering and phosphorylation of the ITAM domain by Src

family kinases (Ghazizadeh et al., 1994; Hamada et al., 1993; Holowka, Sil, Torigoe, & Baird,

2007). This is the first event that leads to further downstream signaling. Blocking Src kinases

with dasatinib prevented TFEB nuclear localization compared to the control cells (Figure 3.2.6B,

orange). This suggests that some aspect of Fcγ receptor signaling is required for TFEB nuclear

localization.

  Next, we blocked actin polymerization using cytochalasin D, which should allow

signalling by engaged Fcγ receptors but block particle internalization. Blocking actin

polymerization also inhibited TFEB nuclear localization relative to the control cells (Figure

3.2.6B, red). We also checked the contributions of ERK, which is known to stimulate the

immune response by activating NF-κB and can directly act on TFEB (Garcı & Rosales, 2001;

Settembre et al., 2011). However, blocking ERK with U0126 did not block TFEB nuclear

localization (Figure 3.2.6B, U0126).

  To further investigate signaling requirements for particle internalization, we targeted

class I PI3K (PI3KCI) which is required for phagocytosis of large particles (Schlam et al., 2015).

Interestingly, blocking PI3KCI with LY294002 led to constitutive TFEB nuclear localization

(Figure 3.2.6B, blue). LY294002 is a pan-PI3K inhibitor that can also inhibit class II and III

PI3K. PI3KCIII is particularly interesting because the PtdIns(3)P generated by Vps34 is

converted by PIKfyve into PtdIns(3,5)P_2 (Vieira et al., 2001). This further supports our results

from Chapter 3.1. Therefore, we specifically targeted PI3KCI using ZSTK474. Inhibition of

PI3KCI blocked TFEB nuclear localization (Figure 3.2.6C, blue). We further checked the requirements of phagocytosis by blocking PLCγ. PtdIns(4,5)P_2 is cleaved by PLCγ into IP3 and DAG, the latter which is required actin independent stimulation of phagocytosis by recruiting PKCε (Botelho et al., 2000; Larsen et al., 2002).Blocking PLCγ with pan-PLC inhibitor U73122 also blocked TFEB nuclear localization (Figure 3.2.6C, green), further supporting a requirement for particle internalization. Taken together, Fcγ receptor signaling mediators that are necessary for particle uptake appear to be required for TFEB nuclear localization following Fcγ receptor activation. Therefore, particle internalization and subsequent phagosome formation may be necessary for TFEB activation following Fcγ receptor engagement.

3.2.5 Particle internalisation but not phagosome maturation is required for TFEB localization by the Fcγ receptor

The signaling components necessary for TFEB nuclear localization suggest that the particle must be internalized to form a phagosome. To test this hypothesis, we challenged RAW

$$
?
$$

| Fcγ receptor signaling | → | Particle internalization | --> | TFEB |
cells with oversized beads opsonized with IgG. Instead of the 3.0 or 3.87 μm beads that were smaller than the cell, these oversized beads were 21.25 μm. Since these beads are opsonized with IgG, the RAW cells will attempt to internalize the beads but become "frustrated" and fail to internalize the particle despite downstream signaling from the receptor. Similar work done by Dr. Gray showed frustrated phagocytosis onto coverslips allowed for Fc receptor signaling, as reported by phosphorylation of Syk (Figure A1.4A) (Gray et al., 2016). Cells challenged with 3.0 μm beads induced TFEB nuclear localization 4.1 ± 0.6 fold over control cells (Figure 3.2.7).

74

Meanwhile, cells challenged with 21.25 μm beads strongly abated TFEB nuclear translocation, with only 1.8 ± 0.6 fold over control. This result suggests phagosomes must form to induce TFEB nuclear localization and that signalling is not sufficient to engage TFEB. These results are consistent with work from our lab that showed frustrated phagocytosis of IgG-opsonized coverslips also blocked TFEB nuclear localization (Figure A1.4B).

While it appears that the particle must be internalized to induce TFEB nuclear localization, we also wondered if phagosome-lysosome fusion is required for TFEB nuclear

$$?$$

| Fcγ receptor signaling | → | Particle internalization | - - > | Phagosome-lysosome fusion | - - > | TFEB |
localization. Our kinetic analysis with phagocytosis of IgG opsonized beads showed TFEB-GFP localized to the nucleus between 30-60 min post-phagocytosis (Figure 3.2.1A). This timing is consistent with the time required for the phagosome to acquire LAMP1, a marker of the late endosome and lysosome (Vieira et al., 2001). To block maturation of the phagosome, we knockdown the Rab7 GTPase. Rab7 activity is required for phagolysosome formation (Harrison et al., 2003).

Two separate sets of Rab7 knockdown were performed using different individual oligonucleotides. To confirm knockdown of Rab7, we performed Western blots following 48 h of siRNA gene silencing (Figure 3.2.8A). Cells knocked-down with oligonucleotide 1 or 2 showed 88 ± 1% and 96 ± 2% reduced Rab7 abundance relative to the non-targeting control oligo. Cells with Rab7 knockdown did not change basal TFEB localization (Figure 3.2.8B). Consistent with our hypothesis, cells knocked-down for Rab7 prevented TFEB nuclear localization with *E. coli*, relative to the no-knockdown condition. Specifically, the TFEB nucleus-to-cytosolic ratio was reduced to 44 ± 10% and 44 ± 18% of the non-targeting condition

75

for the oligonucleotide 1 and 2 respectively. Further work needs to be done to confirm that maturation is impaired in Rab7 knockdown cells. Together, these results suggest that Fcγ receptor signaling leading to particle internalization, phagosome formation, and phagosome maturation are all necessary for TFEB activation following phagocytosis.

Figure 3.1.1: Apilimod depletes PtdIns(3,5)P_2 in RAW macrophages leading to enlarged lysosomes. (A) Structure of apilimod is shown. (B) Quantification of PtdIns(3)P and PtdIns(3,5)P_2 in RAW cells metabolically labeled with ^{3}H-*myo*-inositol and HPLC-coupled flow scintillation. Cells were treated with 20 nM apilimod for 1 h and compared against the DMSO-treated control. Data shown is the mean abundance ± SEM by measuring the amount of each PtdInsP, normalized against the parental PtdIns peak before comparison against the vehicle-treated control. Asterisks (*) indicate statistical significance compared to the DMSO-treated control condition (p<0.05) using Student's t-test (Ho et al., 2015). (C, D) Apilimod induces lysosomal enlargement in RAW macrophages. (C) Lysosomes become clearly visible by differential interference contrast microscopy after 1 h of 20 nM apilimod treatment relative to the vehicle-treated control. (D) Lysosomes can be visualized by fluorescence microscopy when pre-labeled with a fluid-phase marker like lucifer yellow. In vehicle-treated cells, lysosomes are small and numerous, but become greatly enlarged and fewer in number after treatment with 20 nM apilimod for 1 h compared to the vehicle-treated control condition. Scale bars indicate 5 μm.
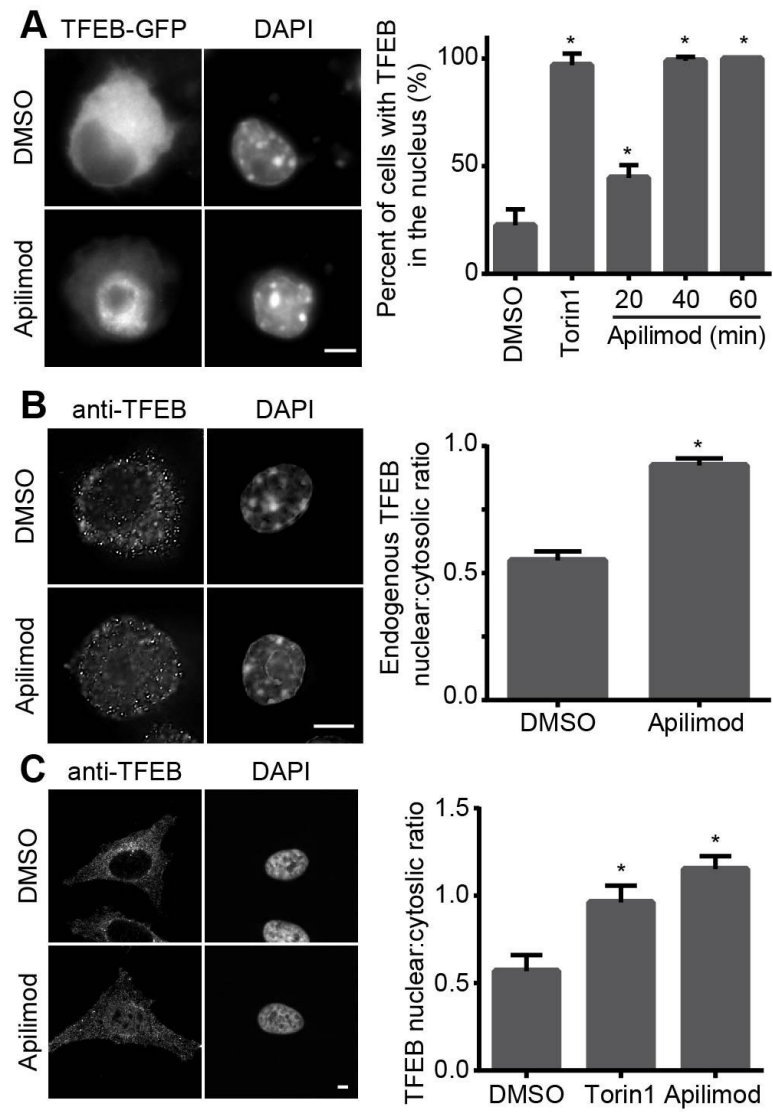

Figure 3.1.2: PIKfyve inhibition with apilimod induces TFEB nuclear localization. (A, B) RAW cells expressing TFEB-GFP (A) or stained for endogenous TFEB (B) treated with DMSO or 20 nM apilimod for 1 h. (C) HeLa cells stained for endogenous TFEB treated with vehicle or 200 nM apilimod for 1 h. Where indicated, the nucleus is counter-stained with DAPI. Nuclear translocation of TFEB was expressed as a percent of cells with greater average nuclear fluorescence compared to the cytosol of TFEB-GFP (A) or the nuclear:cytosolic ratio of their respective mean fluorescence intensity for endogenous TFEB (B, C). Quantifications shown are the mean ± SEM for at least three independent experiments with a minimum of 30 cells counted per condition per experiment. Torin1 is used as a positive control through inhibition of mTOR and applied for 1 h at 100 nM. Asterisks (*) indicate statistical difference compared to the vehicle treated control ($p<0.05$) using one-way ANOVA with Tukey's post-hoc test (A, C) or Student's t-test (B). Scale bars indicate 5 μm.
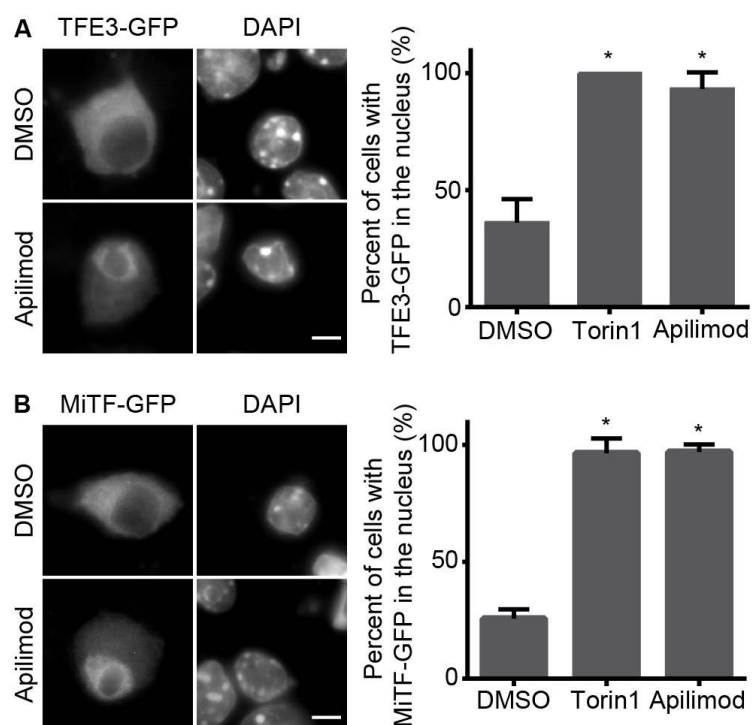

Figure 3.1.3: PIKfyve inhibition also induces nuclear localization of other MiT/TFE family transcription factors. RAW cells transfected with either TFE3-GFP (A) or MiTF-GFP (B) treated with 20 nM apilimod for 1 h or DMSO control. The accompanying quantification shows the percent of cells with greater average fluorescence intensity in the nuclear compared to the cytosol. Where indicated, DAPI is used to stain the nucleus. The accompanying quantifications show the mean $\pm$ SEM for at least three independent experiments with a minimum of 30 cells counted per condition per experiment. Inhibition of mTOR with 100 nM torin1 for 1 h is used as a positive control. Asterisks (*) indicate statistical difference compared to the vehicle-treated control ($p<0.05$) using one-way ANOVA with Turkey's post-hoc test. Scale bars indicate 5 μm.

Figure 3.1.4: Apilimod treatment changes TFEB phosphorylation pattern. Western blot of whole cell lysates run on SDS-PAGE gels supplemented with Phos-tag acrylamide and Mn^{2+}. A representative blot from three independent experiments is shown. TFEB gel mobility of DMSO-treated control cells is compared against 100 nM torin1- and 20 nM apilimod-treated cells for 1 h. Bands appearing higher on the blot have greater phosphorylation. Specificity of anti-TFEB antibody is confirmed with the absence of bands in *tfeb*[-/-] RAW whole cell lysates. For comparison, most bands seen in wild-type RAW lysates collapse into a single fast running band after dephosphorylation with lambda protein phosphatase.

Figure 3.1.5: PIKfyve and mTORC1 function independently. (A) mTORC1 activity based on phosphorylation of p70-S6K. Cells were treated with either vehicle, 20 nM apilimod for the times indicated, or 100 nM torin1 for 1 h as a positive control. A representative blot is shown from four independent experiments. The accompanying quantification shows the mean abundance ± SEM of phospho-p70-S6K at T389 compared to total p70-S6K and normalized against the vehicle-treated control. (B) PtdIns(3,5)P_2 levels during mTORC1 inhibition. PtdInsP were metabolically labelled with ^{3}H-*myo*-insotiol and subjected to HPLC-coupled flow scintillation. Cells were treated with either vehicle, 100 nM torin1 or 20 nM apilimod for 1 h. Shown is the quantification of the mean abundance ± SEM of each PtdInsP normalized against the parental PtdIns and compared against the vehicle-treated control condition. Asterisks (*) indicate statistical difference compared to the vehicle treated control (p<0.05) using multiple Student's t-test with Bonferroni correction.
Figure 3.1.6: ERK2 remains active during PIKfyve inhibition. Western blot analysis of ERK1/2 phosphorylation. Cells were treated with either vehicle, 20 nM apilimod for the times shown, or 10 μM ERK inhibitor U0126 for 1 h as a positive control. (A) Shown is a representative blot of three independent experiments. (B,C) The accompanying quantification shows the mean abundance ± SEM of (B) phospho-ERK2 at T185/Y187 compared to total ERK2 and normalized against the vehicle-treated control or (C) phospho-ERK1 at T202/Y204 compared to total ERK1 and normalized against the vehicle-treated control. Asterisks (*) indicate statistical difference compared to the vehicle treated control (p<0.05) using multiple Student's t-test with Bonferroni correction. Unpublished data.

Figure 3.1.7: PIKfyve inhibition increases inhibition of GSK3α/β. Western blot analysis of GSK3α/β phosphorylation. Cells were treated with vehicle, 20 nM apilimod for the times indicated, or 100 nM torin1 for 1 h as a positive control. A representative image is shown of three independent experiments. The accompanying quantification shows the mean abundance ± SEM of phospho-GSK3α/β at S21/9 respectively compared to total GSK3α/β respectively and normalized against the vehicle-treated control. Asterisks (*) indicate statistical difference compared to the vehicle treated control ($p<0.05$) using multiple Student's t-test with Bonferroni correction. Unpublished data.
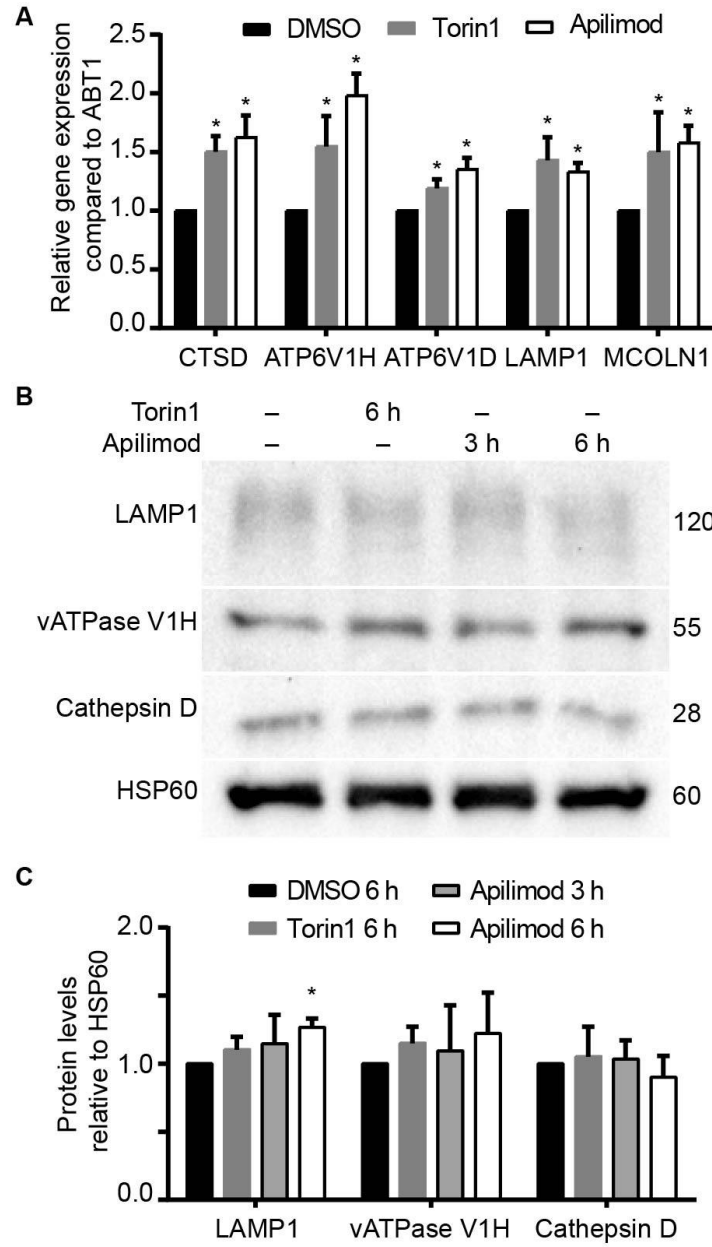

Figure 3.1.8: PIKfyve inhibition increases lysosome gene transcription but not translation. (A) Quantification of select lysosomal gene mRNA by qRT-PCR. Total RNA was extracted from cells treated with vehicle, 100 nM torin1 or 20 nM apilimod for 3 h. Shown is the mean mRNA levels $\pm$ SEM relative to the control gene ABT1 and normalized against the vehicle-treated control condition from seven independent experiments. (B) Western blot of select lysosomal proteins. Whole cell lysates were generated from cells treated with vehicle, 100 nM torin1 for 6 h, or 20 nM apilimod for 3 or 6 h. Representative images are shown with corresponding molecular weights (kDa) shown to the right of the blots. (C) Quantification of lysosomal protein levels from corresponding blots shown in B. Shown is the mean abundance $\pm$ SEM from four independent experiments as compared against HSP60 and normalized against the vehicle-treated control. Asterisks (*) indicate statistical difference compared to the vehicle-treated control ($p<0.05$) using multiple Student's t-test with Bonferroni correction.
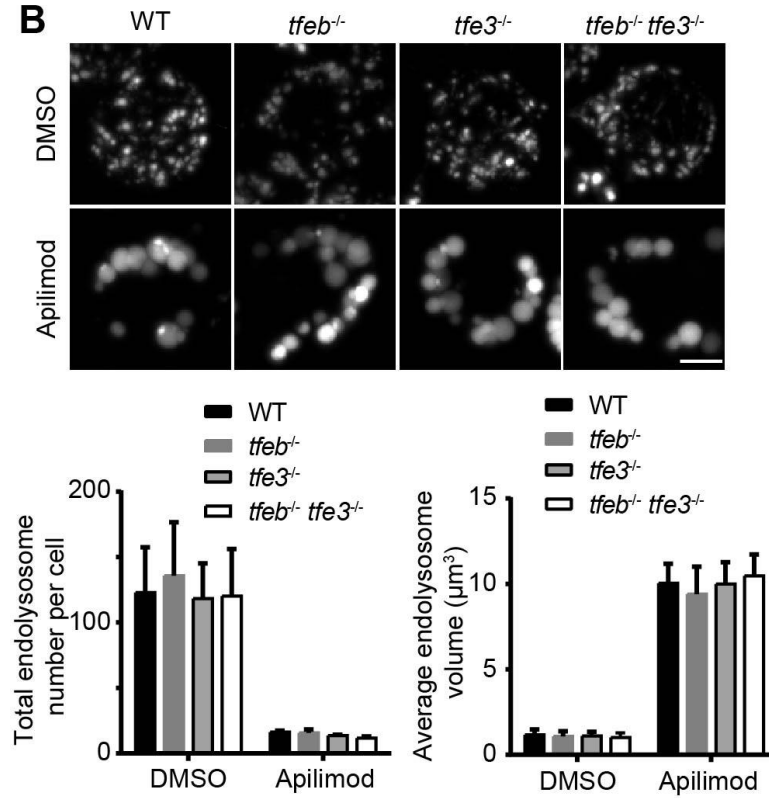

Figure 3.1.9: Lysosome enlargement during PIKfyve inhibition is not abated by *tfeb*[-/-] and or *tfe3*[-/-]. Lysosomes number and size are quantified in wild type, *tfeb*[-/-], *tfe3*[-/-], or *tfeb*[-/-] *tfe3*[-/-] RAW macrophages. (A) Manual quantification of vacuoles in RAW cells. Cells treated with vehicle or 20 nM apilimod for 1 h were imaged live with DIC optics. Here, vacuoles are defined as visible lysosomes whose diameter is equal or greater than 1.5 μm. The accompanying quantifications count the average number of vacuoles ± SEM per cell or the average diameter of vacuoles ± SEM within cells from three independent experiments. (B) Automated counting of lysosome size in RAW cells. Lysosomes were preloaded with lucifer yellow and cells were treated with either vehicle or 20 nM apilimod for 1 h before live-cell imaging. Lysosome number and size are quantified using Icy automated bioimaging analysis software. Quantifications show the average number of lysosomes ± SEM per cell or the average volume of lysosomes ± SEM per cell from five independent experiments. Statistical tests were performed using one-way ANOVA comparing knockout backgrounds against the wild-type background. Scale bars indicate 5 μm.
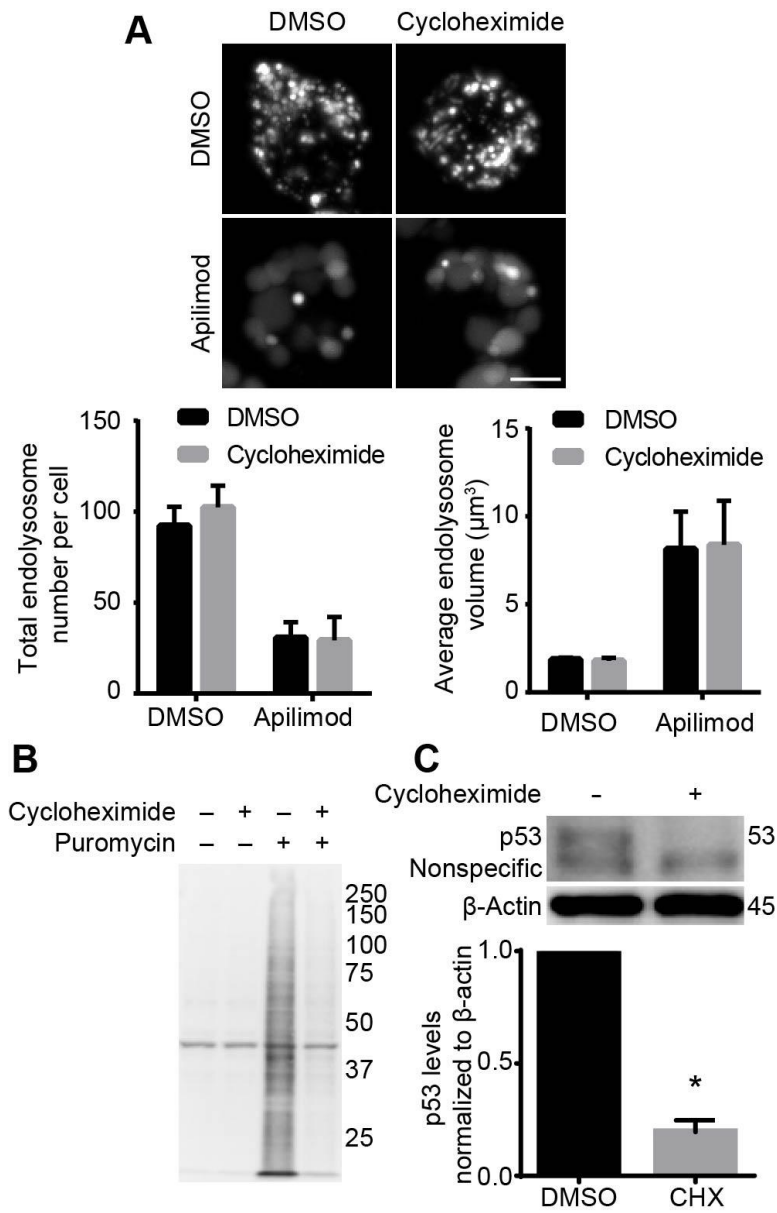

Figure 3.1.10: Protein synthesis does not contribute to lysosome enlargement during PIKfyve inhibition. (A) Morphology of lysosomes in RAW cells pre-labeled with lucifer yellow. Cells were treated with 10 µM cycloheximide or vehicle for 1 h, then treated with vehicle or 20 nM apilimod for 1 h. Quantifications show the average number of lysosomes ± SEM per cell or the average volume of lysosomes ± SEM per cell from three independent trials. Statistical tests were performed using Student's t-test comparing cycloheximide- and vehicle-treated cells. Scale bar indicates 5 µm. (B, C) Confirmation of protein synthesis inhibition with cycloheximide. (B) Western blot analysis of puromycin incorporation into actively synthesizing proteins. RAW cells are treated with either vehicle or 10 µM cycloheximide for 1 h with the addition of 10 µg/mL puromycin 15 min before cell lysis. Shown is a representative image from three independent experiments. (C) Western blot analysis of fast-turnover protein p53 with cycloheximide inhibition from whole cell lysates. Representative image is shown of three independent experiments with molecular weights (kDa) shown to the right of the blot. Cells were treated with vehicle or 10 µM cycloheximide for 1 h. The accompanying quantification shows the mean abundance of p53 relative to β-actin, normalized to the vehicle-treated control sample. Asterisks (*) indicate statistical difference compared to the vehicle-treated control ($p<0.05$) using multiple Student's t-test with Bonferroni correction.
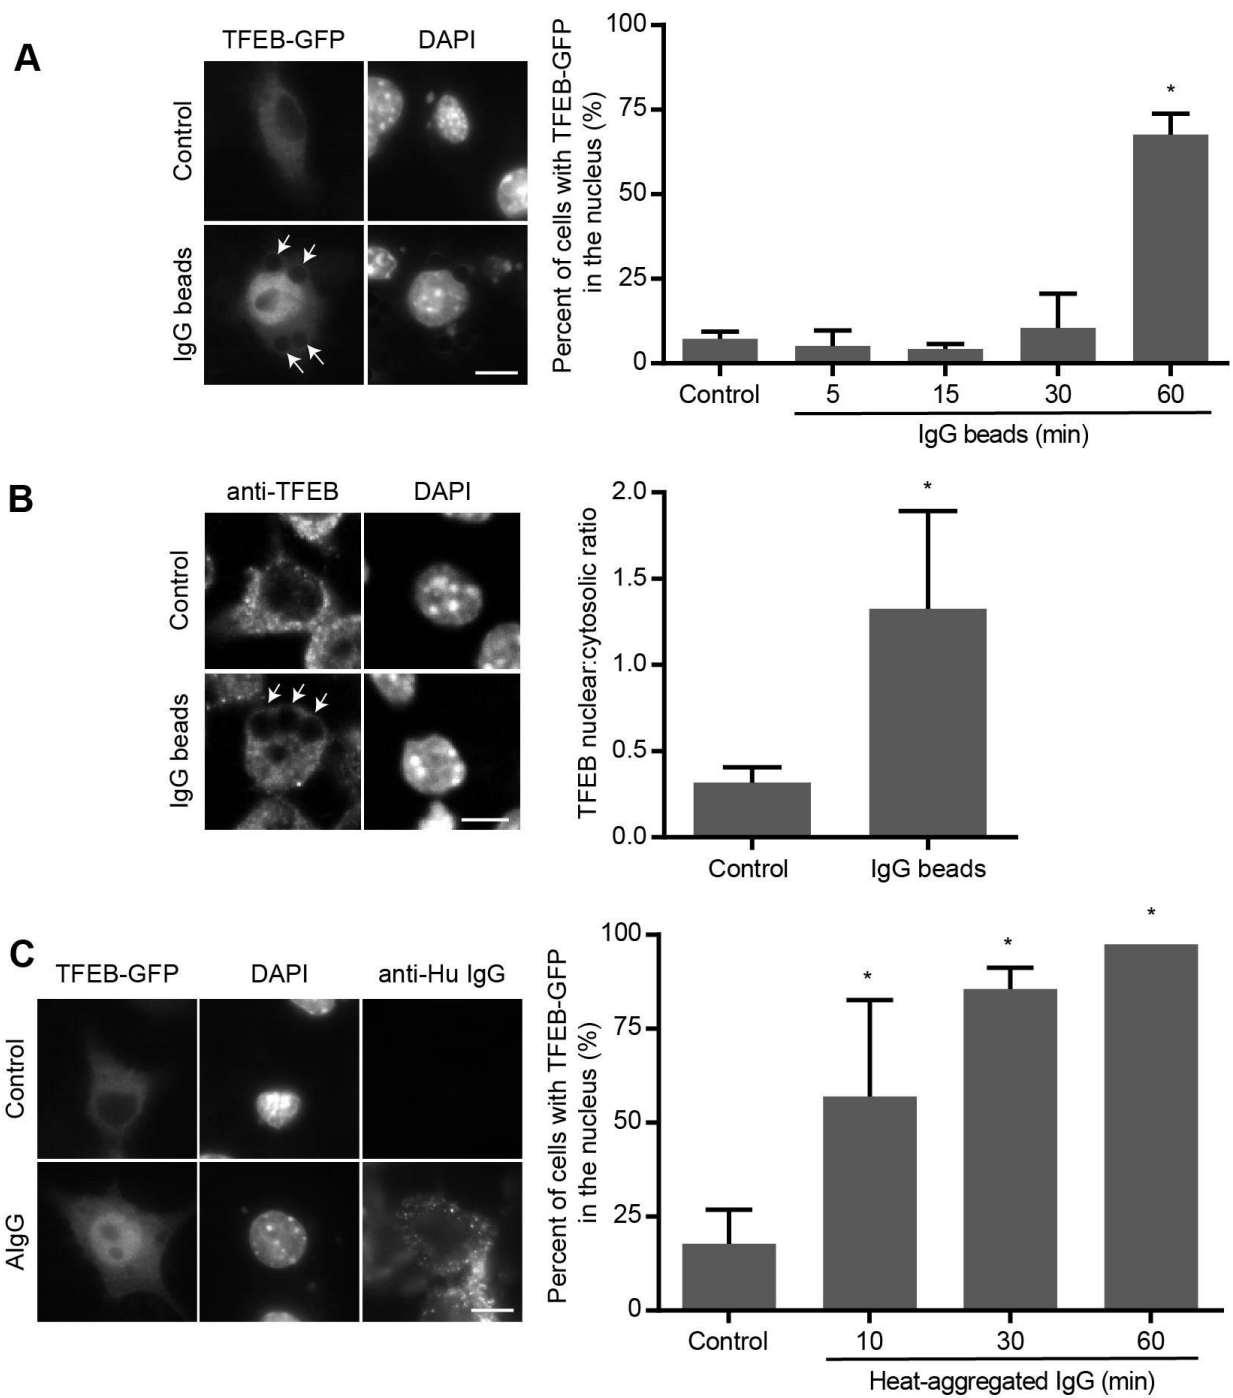

Figure 3.2.1: Engagement of the Fcγ receptor induces TFEB nuclear localization. (A, B) RAW cells expressing TFEB-GFP (A) or stained for endogenous TFEB (B) were stimulated with IgG-opsonized beads. Beads were chased for 60 min unless otherwise indicated. Arrows indicate internalized beads. (C) RAW cells expressing TFEB-GFP were also challenged with heat-aggregated IgG (AIgG). Cells were fixed after the chase times indicated. The nucleus was stained with DAPI where indicated. Nuclear localization of TFEB was expressed as a percent of cells with greater mean fluorescence in the nucleus compared to the cytosol of TFEB-GFP (A, C) or the nuclear-to-cytosolic mean fluorescence intensity ratio for endogenous TFEB (B). Quantifications shown are the mean ± SEM for three independent experiments with at least 30 cells counted per condition per experiment. Asterisks (*) indicate statistical difference compared to the vehicle treated control ($p<0.05$) using one-way ANOVA with Tukey's post-hoc test (A, B) or Student's t-test (C). Scale bars indicate 5 μm.
Figure 3.2.2: Cytokine treatment does not induce TFEB nuclear translocation. RAW cells expression TFEB-GFP were stimulated with INFγ, IL-12, IL-40, or IL-10 for 4 h. Quantification shown represents the percent of cells with greater mean fluorescence in the nucleus compared to the cytosol of TFEB-GFP. Data shown is the mean ± SEM from three independent experiments with at least 30 cells counted per condition per experiment. Cells were treated with 100 nM torin1 for 1 h as a positive control. Asterisks (*) indicate statistical difference compared to the vehicle-treated control ($p<0.05$) using one-way ANOVA with Tukey's post-hoc test.
Figure 3.2.3: TFEB activation with Fcγ receptor engagement enhances lysosome proteolysis. (A) Quantification of select lysosomal genes by qRT-PCR. Total RNA was extracted from basal cells or cells challenged with IgG-opsonized beads for 4 h. Torin1 was used as a positive control at 100 nM for 4 h. Shown is the mean abundance ± SEM relative to the control gene ABT1 and normalized against the vehicle-treated control condition from four independent trials. (B) DQ-BSA proteolysis following Fcγ receptor engagement. RAW cells were challenged with heat-aggregated IgG (AIgG) for the times indicated to pre-active TFEB and to stimulate lysosome biogenesis. Following treatment, cells co-endocytosed DQ-BSA and dextran as a control for internalization. Cells were allowed to degrade the BSA for 1 h. Quantification shown represents the mean fluorescence ± SEM of DQ-BSA normalized to dextran by flow cytometry, from three independent experiments. Asterisks (*) indicate statistical difference compared to the control condition or no IgG stimulation condition (p<0.05) using one-way ANOVA with Tukey's post-hoc test.

Figure 3.2.8: Rab7 is required for TFEB nuclear localization with *E. coli*. (A) Confirmation of

Rab7 knockdown. Rab7 was knocked-down with two rounds of gene silencing with two separate

siRNA oligos against Rab7 or with non-targeting siRNA. The blot shown is a representative

image from three independent experiments. The accompanying quantification shows the mean

abundance ± SEM of Rab7 protein silenced with either Rab7 oligo 1, 2 or non-targeting siRNA.

(B) Rab7 knockdown prevents TFEB nuclear localization with *E. coli* but not IgG-opsonized

beads. RAW cells knocked down for Rab7 or non-targeting siRNA were challenged with IgG-

opsonized beads or E. coli and stained for endogenous TFEB. Where indicated, DAPI was used

to stain the nucleus or the phagocytic particle were fluorescently illuminated. Representative

images are shown from three independent experiments. Quantification shown represents the

mean TFEB nuclear-to-cytosolic ratio ± SEM by normalizing the ratio against the basal cells and

then against the non-targeting control, from three independent experiments. Asterisks (*)

indicate statistical difference between Rab7-knockdown compared to the non-targeting control

($p < 0.05$) using one-way ANOVA with Tukey's post-hoc test or multiple Student's t-test with

Bonferroni correction. Scale bar represents 5 µm.

Chapter 4: Discussion

Increasing lysosome biogenesis is an adaptive strategy adopted by cells under various

forms of cellular stress, including starvation, oxidative stress and immune signaling (Martina &

Puertollano, 2018; Najibi et al., 2016; Roczniak-Ferguson et al., 2012). Enhancing lysosome

biogenesis and related trafficking pathways also has therapeutic value in a variety of diseases

stemming from insufficient autophagy and molecular degradation (Palmieri et al., 2017;

Spampanato et al., 2013). Lysosome biogenesis can be controlled by activating TFEB through

overexpression or altering phosphorylation. To date, six kinases and two phosphatases are

responsible for altering TFEB phosphorylation (Martina & Puertollano, 2018; Puertollano et al.,

2018). Many phosphorylation events alter TFEB localization, modulated by kinases like

mTORC1, ERK2, Akt, MAP4K3 and GSK3β, and phosphatases like calcineurin and PP2A

(Figure 1.1.2, black circles with P). Additionally, TFEB stability can be altered by

phosphorylation by PKCβ (Figure 1.1.2, grey circles with P). Here, we identified two additional

pathways that can induce nuclear localization and activation of TFEB: PIKfyve-inhibition

induced lysosome enlargement and Fcγ receptor mediated phagocytosis.

4.1 PIKfyve regulation of TFEB

4.1.1 TFEB is not required for PIKfyve inhibition-induced lysosome enlargement

PtdIns(3,5)P_2 is necessary for maintenance of numerous lysosomal functions including

autophagosome degradation, ion homeostasis, and maintenance of lysosome size (Dong et al.,

2010; Cole J. Ferguson et al., 2009; Ikonomov, Sbrissa, & Shisheva, 2001). The most obvious

defect due to PtdIns(3,5)P_2 depletion is the dilation of the lysosome, a process that remains

incompletely understood. To date, the prevailing model suggests lysosome enlargement is due to

a failure for membranes to fission from the endolysosomal compartment (Bryant et al., 1998;

Krishna et al., 2016; Rutherford, 2006). Chief among these is the defect in retrograde traffic, necessary for the retrieval of the mannose 6-phosphate receptor from the endosome to the trans-Golgi network (Rutherford, 2006). However, enhanced biosynthesis of lysosomes via TFEB and/or related family members activation has yet to be evaluated.

Our results show that PIKfyve inhibition induced nuclear localization of TFEB (Figure 3.1.2) and its family members, TFE3 and MiTF (Figure 3.1.3). Consistently, others have also shown that PIKfyve inhibition induced TFEB nuclear localization in several cell types (Gayle et al., 2017; W. Wang et al., 2015). Furthermore, nuclear TFEB correlated with transcriptional upregulation of several lysosomal genes (Figure 3.1.8A). Interestingly, the increase in transcription did not lead to enhanced translation over 6 hours, aside from LAMP1 (Figure 3.1.8B,C). This disconnect between transcription and translation may be due to multiple trafficking defects resulting from PIKfyve inhibition. Chronic PIKfyve inhibition impaired recycling of the mannose 6-phosphate receptor from the endosome to the trans-Golgi network, leading to degradation of mannose 6-phosphate receptor (Rutherford, 2006; Y. Zhang et al., 2007). Correspondingly, inactive pro-forms of cathepsin proteases appear to accumulate during prolonged PIKfyve inhibition (Gayle et al., 2017; Y. Zhang et al., 2007). Additionally, PIKfyve-inhibited cells are thought to have impaired autophagosome turnover and increased levels of LAMP2 (Cole J. Ferguson et al., 2009), which may correlate with LAMP1 detected at 6 hours (Figure 3.1.8B,C). Nevertheless, impaired biosynthesis did not abate lysosome enlargement. TFEB and family members appear to be dispensable for lysosome swelling during PIKfyve inhibition when measuring lysosome number and size (Figure 3.1.9, A1.2). Similarly, blocking translation with cycloheximide also did not abate lysosome swelling (Figure 3.1.10). Together,

116

these results suggest lysosome enlargement during acute PIKfyve inhibition do not depend on biosynthesis.

4.1.2 PIKfyve regulation of mTORC1

TFEB activity is understood to be directly regulated by at least six kinases and two phosphatases (Martina & Puertollano, 2018; Puertollano et al., 2018). Loss of phosphorylation is most often associated with nuclear translocation of TFEB. Consistent with this idea, TFEB nuclear localization during PIKfyve inhibition correlated with a loss of phosphorylation, as judged by increased TFEB mobility through Phos-tag gels (Figure 3.1.4). Increased TFEB mobility has also been observed by standard SDS-PAGE gels during PIKfyve inhibition (Gayle et al., 2017). While the Phos-tag assay indicated a decrease in the number of TFEB phosphorylations, it does not provide any information regarding the identity of the residues being modified. Knowing the residues being altered would hint at specific kinases or phosphatases responsible for TFEB dephosphorylation. To this end, very few TFEB phospho-specific antibodies have been generated and only one is commercially available (Settembre et al., 2012; Vega-Rubin-de-Celis et al., 2017). Thus, we assessed the activities of known kinases to determine their relative contributions to TFEB dephosphorylation during PIKfyve inhibition.

The most well-characterized TFEB kinase is mTORC1, which directly modulates S211 phosphorylation. This phospho-site forms a docking site for 14-3-3 which physically masks the nuclear localization sequence upon binding, keeping TFEB inactive and in the cytosol (Roczniak-Ferguson et al., 2012). We postulate that upstream regulators of mTORC1 may also regulate TFEB function. PIKfyve function appears to be necessary for mTORC1 activation in

117

adipocytes (Bridges et al., 2012). Thus, we examined a possible PIKfyve-mTORC1-TFEB pathway. Contrary to this idea, mTORC1 appeared to be active during PIKfyve inhibition when examining the phosphorylation of S6K. These results are consistent with others who show that S6K remains phosphorylated during PIKfyve inhibition (Krishna et al., 2016; W. Wang et al., 2015).

We also evaluated the possibility that mTORC1 controls PIKfyve. In this hypothetical pathway, PtdIns(3,5)P_2 may recruit TFEB to the lysosome similar to recruitment of Tup1 in yeast during galactose metabolism (Han & Emr, 2011). Here, mTORC1 inhibition may reduce PIKfyve activity and reduce PtdIns(3,5)P_2 levels, preventing TFEB recruitment and subsequent phosphorylation. However, PtdIns(3,5)P_2 levels were not reduced during mTORC1 inhibition (Figure 3.1.5).

Together, these results suggest PIKfyve regulation of TFEB acts in parallel to mTORC1. However, we cannot discount the possibility of functionally distinct pools of mTORC1 that may act differently on TFEB and S6K. For example, mTORC1 is thought to be most active when lysosomes are localized peripherally, where Rheb is proximal to growth factor signaling for activation (Korolchuk et al., 2011). Additionally, mTORC1 may act on different pools of substrates differently based on rapamycin inhibition of mTORC1, which has been attributed to substrate affinity to mTORC1 (Kang et al., 2013). Substrates like TFEB and 4E-BP1 are rapamycin insensitive substrates while S6K becomes dephosphorylated in the presence of rapamycin (Settembre et al., 2012; Thoreen et al., 2009). Thus, it may be possible that a PtdIns(3,5)P_2 sensitive pool of mTORC1 regulates TFEB while S6K is regulated by mTORC1 is PtdIns(3,5)P_2 is insensitive.

Similarly, there may also be specific pools of PtdIns(3,5)P_2 that may activate TFEB aside from the bulk PtdIns(3,5)P_2. HPLC-coupled flow scintillation allows for measurement of total PtdIns(3,5)P_2, but does not discriminate between localization or acyl chain content. Thus, we can only conclude that PtdIns(3,5)P_2 did not decrease. However, specific pools of PtdIns(3,5)P_2 may exist. For example, the plasma membrane associated PtdIns(3,5)P_2 observed by Bridges et al. was synthesized by PI3K-C2α-PIKfyve pathway, rather than the canonical Vps34-PIKfyve pathway (Bridges et al., 2012). Another possibility is that PI5P is responsible for TFEB recruitment. PI5P is thought to be primarily generated by dephosphorylation of PtdIns(3,5)P_2, which would also depend on active PIKfyve (Oppelt et al., 2014; Zolov et al., 2012).

4.1.3 PIKfyve regulation of other known TFEB kinases

We further investigated TFEB activation by other known kinases. ERK2 and GSK3β are thought to phosphorylated TFEB at S142 and S134/S138 respectively (Y. Li et al., 2016; Settembre et al., 2011). While we did not observe a difference in ERK2 phosphorylation with apilimod-treatment (Figure 3.1.6B), we did see an increase in GSK3 inhibitory phosphorylation, of both isoforms (Figure 3.1.7). GSK3 preferentially binds "primed" substrates that are pre-phosphorylated four residues C-terminal to the site of phosphorylation. Increased GSK3 phosphorylation at S21 for GSK3α and S9 for GSK3β act as pseudo-substrates and are more likely to block the active site of the kinase, leading to inhibition (Frame et al., 2001). Therefore, we overexpress a constitutively active GSK3β-S9A mutant, preventing the active site from binding its pseudo-substrate (Stambolic & Woodgett, 1994). Cells expressing wild-type GSK3β or GSK3β-S9A did not prevent TFEB nuclear localization in the presence of apilimod (Figure A1.1).

However, we cannot conclude that GSK3β does not act on TFEB during PIKfyve inhibition. Activity of GSK3β is also dependent on phosphorylation of Y216 (Hughes, Nikolakaki, Plyte, Totty, & Woodgett, 1993). Phosphorylation of Y216 may depend on autophosphorylation during synthesis (Cole et al., 2004) or by other kinases like Src (Goc et al., 2014). Also, while we overexpress wild-type GSK3β and GSK3β-S9A, the endogenous GSK3β is still present in these cells. Additionally, GSK3β has been reported in the cytosol and in the nucleus (Bechard & Dalton, 2009). TFEB phosphorylation by GSK3β was shown to occur in the nucleus where TFEB primed with phosphorylation at S142 is recognized by GSK3β (L. Li et al., 2018). This leads to phosphorylation of S138 which activates a nuclear export sequence on TFEB (Y. Li et al., 2016). Finally, GSK3α may also act redundantly with GSK3β since both are inactivated in PIKfyve-inhibited cells. Thus, further investigation must be done to understand the activation, localization, and relative abundance of GSK3β-S9A in RAW macrophages in response to PIKfyve inhibition.

While GSK3β may be required for nuclear exit, TFEB may also require additional signals to induce nuclear import during PIKfyve inhibition. To fully understand how TFEB regulation occurs, proteomic analysis via mass spectrometry would be an invaluable tool to determine changes to post-translational modifications. Individual bands from Phos-tag assay could be cut out and analysed for differences in phosphorylation, which would provide clues about which kinases or phosphatases are necessary for TFEB nuclear localization.

4.1.4 Perspective

Overall, TFEB activation during PIKfyve inhibition may be an attempted adaptive response to lysosome dysregulation. While not necessary for initial lysosome enlargement,

120

TFEB activation in chronically PIKfyve-inhibited cells may occur to activate membrane trafficking pathways and lysosome biogenesis, similar to those observed in lysosome storage disorders (Medina et al., 2011; Spampanato et al., 2013). However, these attempts may be futile since PIKfyve appears to be necessary for biosynthetic traffic of lysosome luminal proteins, leading to build up of inactive lysosomal proteins (Gayle et al., 2017). Therefore, increasing lysosome biogenesis may induce further stress on these cells. Alternatively, PIKfyve-regulation of TFEB may constitute a feedback pathway that cannot be dissected by inhibiting PIKfyve due to pleiotropic effects. As noted above, proteomic studies on TFEB in PIKfyve-inhibited cells may provide target sites to do site-directed mutagenesis to better understand the role of TFEB downstream of PIKfyve. In addition, transcriptomic studies in PIKfyve-inhibited cells in wild-type and TFEB/TFE3-deleted cells may provide clues about the relationship between these two proteins.

4.2 TFEB regulation by phagocytosis

4.2.1 Phagocytosis activates TFEB to enhance proteolysis

Phagocytosis is a necessary component of immune function, sequestering pathogens into phagosomes. These phagosomes undergo maturation and subsequent fusion with the lysosome for degradation. Impaired degradation of cargo can prevent further phagocytosis of pathogens (Wong et al., 2017). Thus, phagocytes may benefit from increasing lysosome biogenesis through TFEB activation to accelerate phagosome breakdown and neutralization of potential threats. Here we show that Fcγ receptor activation induced TFEB nuclear localization (Figure 3.2.1). Phagocytosis of IgG-opsonized beads or endocytosis of heat-aggregated IgG were both sufficient to activate TFEB. Interestingly, Fcγ receptor-mediated phagocytosis selectively upregulated

121

some lysosomal genes, but not all (Figure 3.2.3A). Compared to mTORC1 inhibition with torin1 which upregulated all lysosomal genes tested (Figure 3.2.3, torin1), phagocytosis of IgG-opsonized beads selectively upregulated mRNA levels of *ATP6V1H* and protease *CTSD*, but not membrane protein *LAMP1* or calcium channel *MCOLN1* (Figure 3.2.3, IgG beads). Protein abundance of these genes (Figure A2.1A) agreed with the qRT-PCR data. This data suggests that Fcγ receptor activation does not induce complete lysosome biogenesis leading to more lysosomes. Instead, existing lysosomes were augmented and became "super active." Increased proteolysis and acidification of the lysosome was also observed in dendritic cells (Samie & Cresswell, 2015). Additionally, we observed no difference in the number of LAMP1 positive structures between cells stimulated with heat-aggregated IgG and control cells (Figure A1.3), further strengthening our hypothesis.

The selective increase in lysosome gene transcription may be attributed to other transaction factors, miRNA, and/or modifications to TFEB in the nucleus. As opposed to TFEB, ZKSCAN3 is a transcriptional repressor in fed-cells, responsible for regulating over 60 lysosomal genes (Chauhan et al., 2013). When cells undergo starvation, ZKSCAN3 exits the nucleus at the same time TFEB enters the nucleus to upregulate CLEAR gene transcription (Chauhan et al., 2013). Other transcription factors may also be activated in response to phagocytosis, such as NF-kB that modulates cytokine release (Garcı & Rosales, 2001). Additionally, microRNAs are known to modulate large sets of genes and are activated in many immune cells during inflammation (O'Connell, Rao, & Baltimore, 2012). Interestingly, TFEB is under direct regulation by miR-128 which supresses CLEAR network gene expression (Sardiello et al., 2009). Finally, TFEB can be post-translationally modified with SUMO or acetyl groups that can alter the binding of TFEB to specific promoters (Figure 1.1.2) (Bao et al., 2016; Miller

122

et al., 2005; J. Zhang et al., 2018). It would be interesting to determine the potential interplay between TFEB and other regulatory factors that may impinge on TFEB activity to selectively control a subset of lysosomal genes.

Nevertheless, cells with "super active" lysosomes following Fcγ receptor activation were more proteolytic (Figure 3.2.3B) and were better killers of live *E. coli* than their control counterparts (Figure A2.2). The increase in bacterial killing was dependent on TFEB as both increases to CTSD and ATP6V1H protein levels (Figure A2.1B) and bacterial killing (Figure A2.2, right side) were abated in TFEB-silenced cells. Together, these results suggest Fcγ receptor activation, leads to TFEB-mediated hyperactivation of existing lysosomes. Aside from the Fcγ receptor, TFEB also becomes activated when cells are challenged with unopsonized *E. coli* (Figure 3.2.8B). This is consistent with macrophage stimulation with *S. aureus*, leading to TFEB-dependent upregulation of pro-inflammatory cytokines (Visvikis et al., 2014). However, cytokines themselves were unable to stimulate TFEB activation (Figure 3.2.2).

Thus, it would be interesting to determine the range of phagocytic signals that stimulate TFEB activation. A particularly interesting example is the clearance of apoptotic bodies. Apoptotic cells can be recognized by receptors like Tim4 and induce anti-inflammatory activation of macrophages (Miyanishi et al., 2007; Szondy, Sarang, Kiss, Garabuczi, & Köröskényi, 2017). Additionally, apoptotic cells can also be phagocytosed by other cell types such as epithelial cells (Monks et al., 2005). It would be interesting to see whether non-phagocytic cells also benefit from TFEB activation to accelerate degradation of phagosomes.

4.2.2 Fcγ receptor-to-TFEB signaling

We also aimed to understand how TFEB is regulated during phagocytosis. Since activation of TFEB often depends on phosphorylation, we attempt to characterize changes to TFEB phosphorylation using mobility shift assays with standard SDS-PAGE gels (Figure 3.2.4 A,B) and Phos-tag gels (Figure 3.2.4 C,D). In addition to total TFEB antibody (Figure 3.2.4 A,C), we also attempt to characterize changes in S142 phosphorylation (Figure 3.2.4 B,D). In all cases, TFEB displayed faster mobility in cells that phagocytosed IgG-opsonized beads compared to resting cells. For comparison, unopsonized *E. coli* and mTORC1 inhibition also increased TFEB mobility, resulting in similar patterns to IgG. Interestingly, blots with pS142-TFEB antibody also shifted suggesting this phosphorylation is retained during phagocytosis (Figure 3.2.4 B,D). Analysis of mTORC1 activity via S6K phosphorylation suggests mTORC1 remains active during phagocytosis (Figure 3.2.5).

While mTORC1 inactivation may not be responsible for TFEB nuclear localization during phagocytosis, phagosome-lysosome fusion may be necessary for TFEB activation. This is supported by several lines of evidence. First, blocking Fcγ receptor signaling leading to actin polymerization inhibited TFEB activation (Figure 3.2.6). Active Src/Syk (dasatinib, orange bars), PI3KCI (ZSTK474, blue bars), and PLCγ (U73122, green bars) were necessary for TFEB nuclear localization. Second, phagosome formation was necessary for TFEB activation. Blocking actin polymerization with cytochalasin D also kept TFEB in the cytosol when cells were challenged with IgG-opsonized beads (Figure 3.2.6, red bars). Additionally, TFEB was cytosolic in cells unable to internalize IgG-opsonized oversized beads (Figure 3.2.7). This was consistent with cytosolic TFEB in cells unable to phagocytose IgG-opsonized coverslips (Figure A1.4B), despite Fcγ receptor activation as reported by increase in phospho-Syk (Figure A1.4A). Finally, blocking phagosome maturation of *E. coli* by silencing Rab7 also prevented TFEB activation

(Figure 3.2.8). Consistently, blocking phagosome-lysosome fusion by chelating Ca^{2+} with

BAPTA-AM or siRNA knockdown of MCOLN1 also blocked TFEB nuclear localization (Figure

A2.3) (Dayam et al., 2015). Given the requirement for lysosomal calcium and mucolipin-1, we

speculate that activity of calcium-dependent kinases or phosphatases may altered in response to

phagocytosis and lysosome-phagosome fusion to facilitate TFEB nuclear translocation.

Proteomic analysis of TFEB by mass spectrometry would provide clues regarding specific

kinases or phosphatases responsible for TFEB activation during phagocytosis.

4.2.3 Perspective

Enhancing lysosome biogenesis appears to be an adaptive strategy utilized by phagocytes

to promote degradation of phagocytic cargo. By supplementing existing lysosomes with more

hydrolases and V-ATPase components, phagocytes maximize their bactericidal potential. Indeed,

dendritic cells can switch between major histocompatibility complex class I (MHC-I)-mediated

antigen presentation to MHC-II upon TFEB activation, associated with increased lysosomal

activity and proteolytic activity (Samie & Cresswell, 2015). With the rise of antibiotic resistant

bacteria, TFEB activators may be worth investigating as a possible supplement to fight certain

types of infection. Additionally, other phagocytes like neutrophils may also benefit from TFEB

activation during infection. While neutrophils are generally not long-lived, they can last for at

least one day after activation in vivo. Thus, transcriptional changes in neutrophils may be of

relevance. Neutrophils have four lysosome-related organelles, or granules (Cowland &

Borregaard, 2016). These granules differ in their luminal content and propensity to be secreted.

Since TFEB enhances exocytosis during lysosome storage (Medina et al., 2011), we speculate

that TFEB activation may play a role in granule biogenesis and secretion. Thus, the spectrum of

125

TFEB-mediated responses in various immune cells should be considered and investigated further.

To counter immune-cell function, many pathogens may have also evolved strategies to avoid TFEB-dependent immune responses. For example, *Mycobacterium* can evade the lysosome by blocking phagosome maturation. Phagosomes containing *Mycobacterium* fail to acquire LAMP1 and these pathogens persist within the phagosome (Clemens, Lee, & Horwitz, 2002; Via et al., 1997). Interestingly, *M. tuberculosis* can modulate microRNA-33 to downregulate autophagy effectors, leading to depressed TFEB function (Ouimet et al., 2016). Similarly, live *Salmonella* can evade TFEB activation. Macrophages that phagocytose *Salmonella* fail to activate TFEB, a process dependent on several bacterial virulence factors including PhoP, SifA, and SopD (Escobar, 2017). In contrast, deletion of these virulence factors or dead-Salmonella allowed TFEB nuclear localization (Escobar, 2017). Other pathogens may manipulate TFEB for its own benefit. Human immunodeficiency virus (HIV) infection of macrophages appears to initially upregulate autophagy, promoting viral replication (Campbell, Rawat, Bruckman, & Spector, 2015). Late in the infection, HIV can also produce negative regulatory factor (NEF), which leads to TFEB phosphorylation to prevent HIV from being degraded (Campbell et al., 2015). Other pathogens have likely evolved additional strategies to manipulate TFEB and should be investigated further.

Chapter 5: Conclusion

Induction of lysosome biogenesis and autophagy through TFEB-activation is an adaptive strategy adopted in response to numerous cellular stressors. Here, we identify two additional pathways that lead to TFEB activation.

First, PIKfyve inhibition leads to lysosome enlargement which may be exacerbated by TFEB-induced lysosome biogenesis. Contrary to our original hypothesis, TFEB and general biosynthesis were dispensable for acute lysosome enlargement. The specific role of TFEB during PIKfyve inhibition, whether beneficial or detrimental, remains to be seen. Nevertheless, PIKfyve inhibition appeared to be correlated with GSK3 inhibition, a known kinase of TFEB. While further work must be done to understand the role of GSK3 inhibition in this pathway, this study was the first to characterize a relationship between GSK3 and PIKfyve, to our knowledge.

Secondly, lysosome biogenesis may promote degradation of phagocytic cargo. Consistent with our initial hypothesis, phagocytosis of various immune-based particles promoted TFEB activation, enhancing proteolysis and bacterial killing. Here, the activation of TFEB appeared to depend on phagosome formation and maturation. Thus, TFEB activation may confer immune-related benefits during immunosuppression or persistent infections. Further work should be done to identify the specific kinase or phosphatase modulating TFEB localization following phagocytosis.

Overall, our work expands on the growing list of regulators and pathways that modulate TFEB activity. Understanding the full breadth of TFEB modulators will allow for the development of novel therapeutics towards diseases that can be altered by TFEB activation or suppression.

Appendix
Figure A1.1: Effect of constitutively active GSK3β on TFEB nuclear localization. Cells co-expressed TFEB-GFP and either wild-type GSK3β, constitutively active GSK3β-S9A, or RFP as a transfection control. Cells were treated with vehicle or 20 nM apilimod for 40 minutes. Quantification shown represents the mean ± SEM percent of cells with greater nuclear TFEB-GFP fluorescent intensity than the cytosol in cells co-expressing RFP or GSK3β. Statistical tests were performed using one-way ANOVA comparing RFP- or GSK3β-expressing cells.
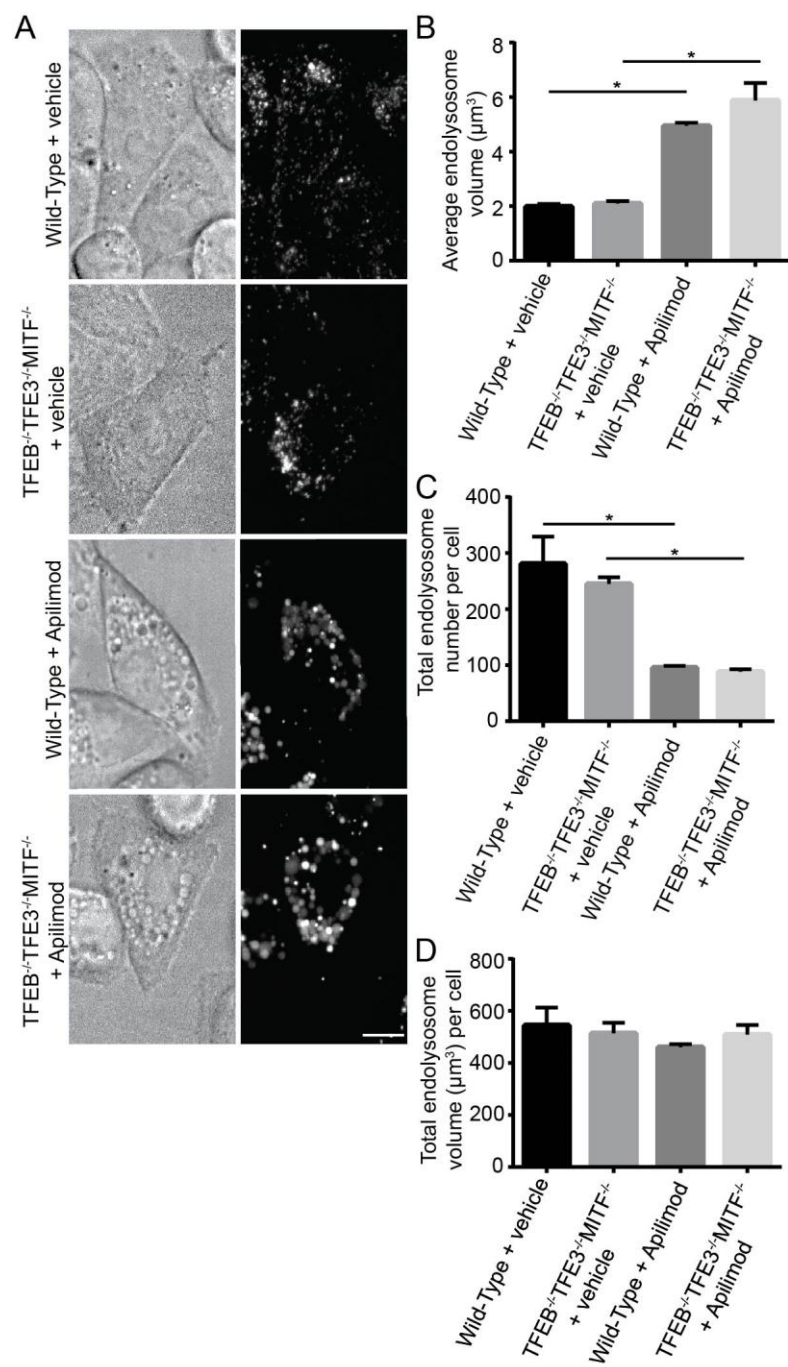

Figure A1.2: Triple knockout of MiT/TFE family members does not reduce lysosome enlargement. Lysosomes of wild type HeLa cells and HeLa cells deleted for $tfeb^{-/-}$, $tfe3^{-/-}$, $mitf^{-/-}$ were pre-labeled with fluorescent dextran and subjected to 50 nM apilimod for 1 h or vehicle. (A) Cells were imaged live and Z-stacks were analyzed for (B) lysosome number, (C) volume of individual lysosomes, or (D) total lysosome volume. Shown is the mean ± SEM from 3 independent experiments with 15-20 cells counted per experiment. Asterisk (*) indicates statistical difference relative to respective controls, as shown by the horizontal bar, using ($p<0.05$) one-way ANOVA with Tukey's post-hoc test. No difference was observed between wild-type and triple knockout HeLa cells for changes during apilimod treatment. Scale bar = 10 μm. Work performed by Golam Saffi (Choy et al., 2018).

134
Figure A1.3: Fcγ receptor engagement does not change lysosome number. RAW cells were stimulated with heat-aggregated IgG (AIgG) for 1.5 h, then stained for were stained for LAMP1. Z-stacks from whole cells were acquired and analyzed for number of LAMP1 positive structures. Quantification shown represents the mean number ± SEM of LAMP1 positive structures from three independent experiments. One-way ANOVA statistical analysis ($p<0.05$) showed no difference between control cells and torin1 (TOR) treatment or AIgG treatment. Work performed by Dr. Matthew Gray (Gray et al., 2016).

Figure A1.4: Frustrated phagocytosis activates Fcγ receptor signaling but does not activate TFEB. Coverslips were coated in BSA and opsonized with anti-BSA IgG. RAW cells were parachuted onto the coverslips. (A) Phosphorylation of Syk as a measure of Fcγ receptor activation. Western blot analysis from whole cell lysates following 1 h incubation on IgG-opsonized coverslips compared to unopsonized coverslips. Shown is a representative image from 7 independent experiments. Quantification shown represents that mean abundance ± SEM of pSyk normalized against total Syk, each normalized against HSP60. (B) RAW cells expressing TFEB-GFP were parachuted onto IgG-opsonized for frustrated phagocytosis (FP) or non-opsonized coverslips. IgG was detected with a secondary antibody. Torin1 was used as a positive control for TFEB nuclear localization. Shown are representative images from three independent experiments. Scale bar represents 10 µm. (C) Quantification of TFEB-GFP localization from frustrated phagocytosis in (B). Asterisks (*) indicate statistical difference compared to the control condition (p<0.05) using Student's t-test. Work performed by Dr. Matthew Gray (Gray et al., 2016).
Figure A2.1: Fcγ receptor phagocytosis increases protein abundance of some lysosomal proteins. (A) Western blot of whole cell lysates after phagocytosis of IgG-opsonized beads (OB). Protein abundance was compared against torin1 (TOR) treated cells as a positive control. Shown is a representative image from for seven independent experiments for CTSD and ATP6V1H and three independent experiments for LAMP1. Molecular weights are provided to the right of the blot. The accompanying quantification shows mean abundance ± SEM of the respective proteins normalized against HSP60 abundance. (B) qRT-PCR analysis of whole cell lysates after phagocytosis of IgG-opsonized beads (OB), gene silenced with TFEB or non-targeting (NT) oligonucleotides. The quantification shown represents mean relative mRNA abundance ± SEM from four independent experiments. Asterisks (*) indicate statistical difference compared to the control condition ($p<0.05$) using one-way ANOVA with Tukey's post-hoc test. Work performed by Dr. Matthew Gray (Gray et al., 2016).
Figure A2.2: Pre-stimulation of the Fcγ receptor enhances bacterial killing. RAW cells, gene silenced with TFEB or non-targeting (NT) oligonucleotides, were stimulated with heat-aggregated IgG (AIgG) for 3.5 hours. Following initial stimulation, RAW cells were challenged with DH5α *E. coli*. RAW cells were either lysed immediately to determine the number of *E. coli* internalized (black bars) or allowed to degrade the *E. coli* for 5 hours (white bars). Shown is the normalized mean ± SEM number of *E. coli* from three independent experiments. Asterisks (*) indicate statistical difference compared to the control condition ($p<0.05$) using Student's t-test Work performed by Dr. Matthew Gray (Gray et al., 2016).
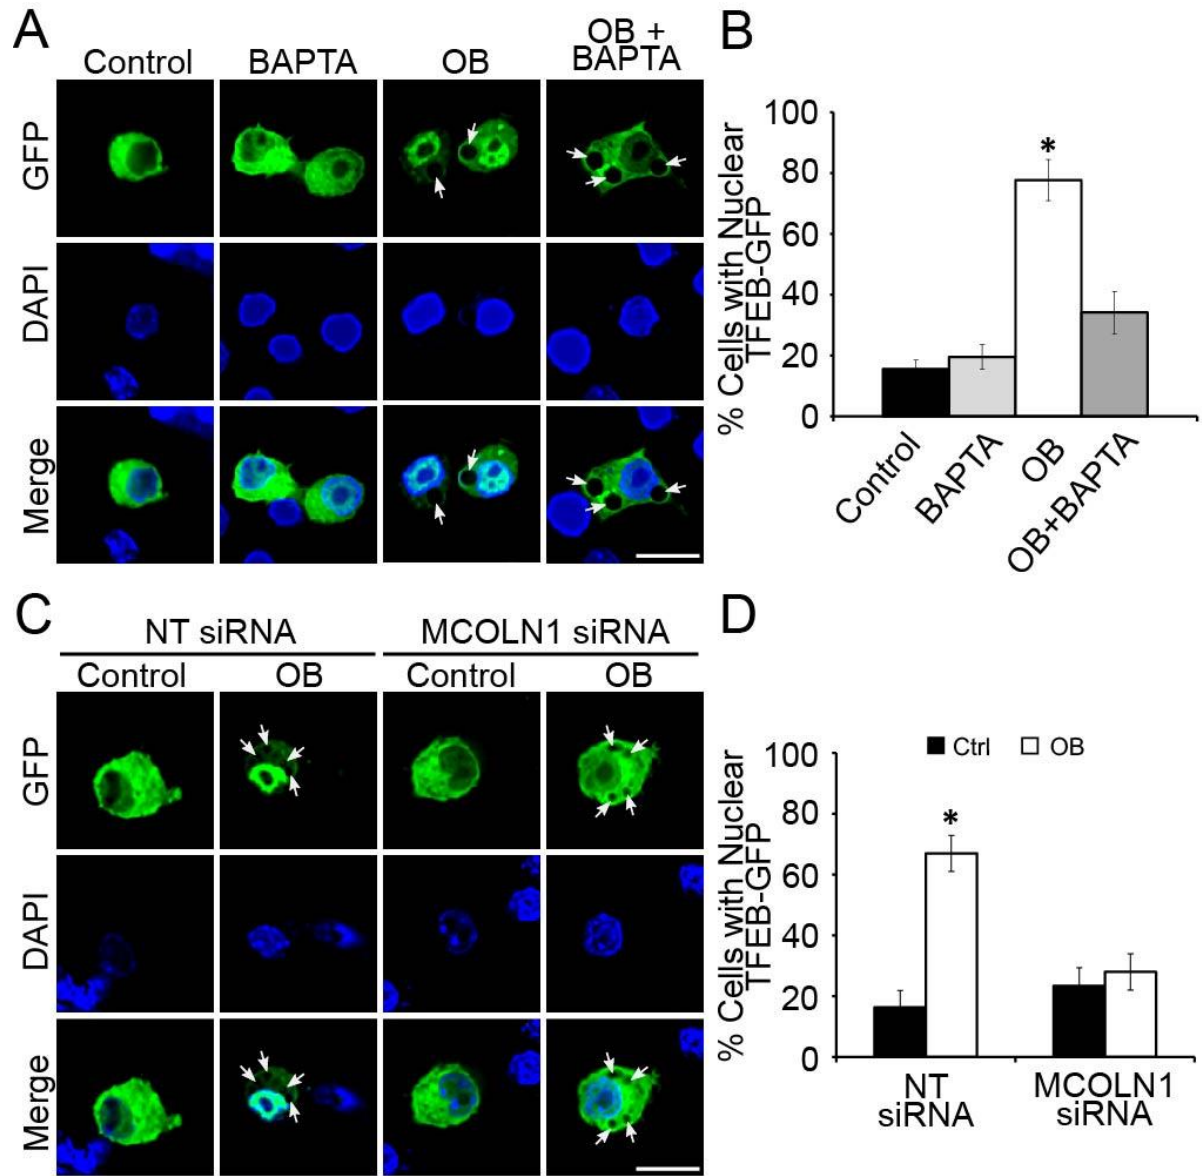

Figure A2.3: TFEB nuclear localization depends on Ca^{2+} release from mucolipin-1. (A, B) RAW cells expressing TFEB-GFP were challenged with BAPTA-AM prior to phagocytosis of opsonized beads (OB). (A) Representative images are shown. (B) Quantification shown represents mean number of cells ± SEM with TFEB-GFP in the nucleus from three independent experiments. Asterisks (*) indicate statistical difference compared to the control condition (p<0.05) using one-way ANOVA followed by Tukey's post-hoc test. (C, D) RAW cells were silenced with MCOLN1 or non-targeting (NT) siRNA, prior to phagocytosis or OB. (C) Representative images are shown. (D). Quantification shown represents mean number of cells ± SEM with TFEB-GFP in the nucleus from three independent experiments. Asterisks (*) indicate statistical difference compared to the control condition (p<0.05) using Student's t-test. DAPI is used as a nuclear counter-stain where indicated. Arrows denote presence of OB. Scale bars represent 10 µm. Work performed by Dr. Matthew Gray (Gray et al., 2016).
